Abstract

Planning in partially observable environments remains a challenging problem, despite significant recent advances in offline approximation techniques. A few online methods have also been proposed recently, and proven to be remarkably scalable, but without the theoretical guarantees of their offline counterparts. Thus it seems natural to try to unify offline and online techniques, preserving the theoretical properties of the former, and exploiting the scalability of the latter. In this paper, we provide theoretical guarantees on an anytime algorithm for POMDPs which aims to reduce the error made by approximate offline value iteration algorithms through the use of an efficient online searching procedure. The algorithm uses search heuristics based on an error analysis of lookahead search, to guide the online search towards reachable beliefs with the most potential to reduce error. We provide a general theorem showing that these search heuristics are admissible, and lead to complete and $\epsilon$-optimal algorithms. This is, to the best of our knowledge, the strongest theoretical result available for online POMDP solution methods. We also provide empirical evidence showing that our approach is also practical, and can find (provably) near-optimal solutions in reasonable time.

1 Introduction

Partially Observable Markov Decision Processes (POMDPs) provide a powerful model for sequential decision making under state uncertainty. However exact solutions are intractable in most domains featuring more than a few dozen actions and observations. Significant efforts have been devoted to developing approximate offline algorithms for larger POMDPs [1, 2, 3, 4]. Most of these methods compute a policy over the entire belief space. This is both an advantage and a liability. On the one hand, it allows good generalization to unseen beliefs, and this has been key to solving relatively large domains. Yet it makes these methods impractical for problems where the state space is too large to enumerate. A number of compression techniques have been proposed, which handle large state spaces by projecting into a sub-dimensional representation [5, 6]. Alternately online methods are also available [7, 8, 9, 10, 11]. These achieve scalability by planning only at execution time, thus allowing the agent to only consider belief states that can be reached over some (small) finite planning horizon. However despite good empirical performance, both classes of approaches lack theoretical guarantees on the approximation. So it would seem we are constrained to either solving small to mid-size problems (near-)optimally, or solving large problems possibly badly.

This paper suggests otherwise, arguing that by combining offline and online techniques, we can preserve the theoretical properties of the former, while exploiting the scalability of the latter. In previous work [11], we introduced an anytime algorithm for POMDPs which aims to reduce the error made by approximate offline value iteration algorithms through the use of an efficient online searching procedure. The algorithm uses search heuristics based on an error analysis of lookahead search, to guide the online search towards reachable beliefs with the most potential to reduce error. In
this paper, we derive formally the heuristics from our error minimization point of view and provide theoretical results showing that these search heuristics are admissible, and lead to complete and \( \varepsilon \) -optimal algorithms. This is, to the best of our knowledge, the strongest theoretical result available for online POMDP solution methods. Furthermore the approach works well with factored state representations, thus further enhancing scalability, as suggested by earlier work [2]. We also provide empirical evidence showing that our approach is computationally practical, and can find (provably) near-optimal solutions within a smaller overall time than previous online methods.

2 Background: POMDP

A POMDP is defined by a tuple \( (S, A, \Omega, T, R, O, \gamma) \) where \( S \) is the state space, \( A \) is the action set, \( \Omega \) is the observation set, \( T : S \times A \times S \rightarrow [0,1] \) is the state-to-state transition function, \( R : S \times A \rightarrow \mathbb{R} \) is the reward function, \( O : \Omega \times A \times S \rightarrow [0,1] \) is the observation function, and \( \gamma \) is the discount factor. In a POMDP, the agent often does not know the current state with full certainty, since observations provide only a partial indicator of state. To deal with this uncertainty, the agent maintains a belief state \( b(s) \), which expresses the probability that the agent is in each state at a given time step. After each step, the belief state \( b \) is updated using Bayes rule. We denote the belief update function \( b' = \tau(b, a, o) \), defined as \( b'(s') = \eta O(o, a, s') \sum_{s \in S} T(s, a, s') b(s) \), where \( \eta \) is a normalization constant ensuring \( \sum_{s \in S} b'(s) = 1 \).

Solving a POMDP consists in finding an optimal policy, \( \pi^* : \Delta S \rightarrow A \), which specifies the best action \( a \) to do in every belief state \( b \), that maximizes the expected return (i.e., expected sum of discounted rewards over the planning horizon) of the agent. We can find the optimal policy by computing the optimal value of a belief state over the planning horizon. For the infinite horizon, the optimal value function is defined as \( V^*(b) = \max_{a \in A} [R(b, a) + \gamma \sum_{o \in \Omega} P(o|b, a) V^*(\tau(b, a, o))] \), where \( R(b, a) \) represents the expected immediate reward of doing action \( a \) in belief state \( b \) and \( P(o|b, a) \) is the probability of observing \( o \) after doing action \( a \) in belief state \( b \). This probability can be computed according to \( P(o|b, a) = \sum_{s' \in S} O(o, a, s') \sum_{s \in S} T(s, a, s') b(s) \). We also denote the value \( Q^*(b, a) \) of a particular action \( a \) in belief state \( b \), as the return we will obtain if we perform \( a \) in \( b \) and then follow the optimal policy \( Q^*(b, a) = R(b, a) + \gamma \sum_{o \in \Omega} P(o|b, a) V^*(\tau(b, a, o)) \). Using this, we can define the optimal policy \( \pi^*(b) = \arg\max_{a \in A} Q^*(b, a) \).

3 Online Search in POMDPs

Contrary to offline approaches, which compute a complete policy determining an action for every belief state, an online algorithm takes as input the current belief state and returns the single action which is the best for this particular belief state. The advantage of such an approach is that it only needs to consider belief states that are reachable from the current belief state. This naturally provides a small set of beliefs, which could be exploited as in offline methods. But in addition, since online planning is done at every step (and thus generalization between beliefs is not required), it is sufficient to calculate only the maximal value for the current belief state, not the full optimal \( \alpha \)-vector. A lookahead search algorithm can compute this value in two simple steps.

First we build a tree of reachable belief states from the current belief state. The current belief is the top node in the tree. Subsequent belief states (as calculated by the \( \tau(b, a, o) \) function) are represented using OR-nodes (at which we must choose an action) and actions are included in between each layer of belief nodes using AND-nodes (at which we must consider all possible observations). Note that in general the belief MDP could have a graph structure with cycles. Our algorithm simply handle
such structure by unrolling the graph into a tree. Hence, if we reach a belief that is already elsewhere in the tree, it will be duplicated.\footnote{We are considering using a technique proposed in the LAO* algorithm \cite{ross1990efficient} to handle cycle, but we have not investigated this fully, especially in terms of how it affects the heuristic value presented below.}

Second, we estimate the value of the current belief state by propagating value estimates up from the fringe nodes, to their ancestors, all the way to the root. An approximate value function is generally used at the fringe of the tree to approximate the infinite-horizon value. We are particularly interested in the case where a lower bound and an upper bound on the value of the fringe belief states is available, as this allows us to get a bound on the error at any specific node. The lower and upper bounds can be propagated to parent nodes according to:

\[
U_T(b) = \begin{cases} 
U(b) & \text{if } b \text{ is a leaf in } T, \\
\max_{a \in A} U_T(b, a) & \text{otherwise};
\end{cases}
\]

\[
U_T(b, a) = R_B(b, a) + \gamma \sum_{o \in \Omega} P(o|b, a)U_T(\tau(b, a, o));
\]

\[
L_T(b) = \begin{cases} 
L(b) & \text{if } b \text{ is a leaf in } T, \\
\max_{a \in A} L_T(b, a) & \text{otherwise};
\end{cases}
\]

\[
L_T(b, a) = R_B(b, a) + \gamma \sum_{o \in \Omega} P(o|b, a)L_T(\tau(b, a, o));
\]

where \(U_T(b)\) and \(L_T(b)\) represent the upper and lower bounds on \(V^*(b)\) associated to belief state \(b\) in the tree \(T\), \(U_T(b, a)\) and \(L_T(b, a)\) represent corresponding bounds on \(Q^*(b, a)\), and \(L(b)\) and \(U(b)\) are the bounds on fringe nodes, typically computed offline.

Performing a complete \(k\)-step lookahead search multiplies the error bound on the approximate value function used at the fringe by \(\gamma^k\) \cite{ross1990efficient}, and thus ensures better value estimates. However, it has complexity exponential in \(k\), and may explore belief states that have very small probabilities of occurring (and an equally small impact on the value function) as well as exploring suboptimal actions (which have no impact on the value function). We would evidently prefer to have a more efficient online algorithm, which can guarantee equivalent or better error bounds. In particular, we believe that the best way to achieve this is to have a search algorithm which uses estimates of error reduction as a criteria to guide the search over the reachable beliefs.

4 Anytime Error Minimization Search

In this section, we review the Anytime Error Minimization Search (AEMS) algorithm we had first introduced in \cite{ross2004efficient} and present a novel mathematical derivation of the heuristics that we had suggested. We also provide new theoretical results describing sufficient conditions under which the heuristics are guaranteed to yield \(\epsilon\)-optimal solutions.

Our approach uses a best-first search of the belief reachability tree, where error minimization (at the root node) is used as the search criteria to select which fringe nodes to expand next. Thus we need a way to express the error on the current belief (i.e. root node) as a function of the error at the fringe nodes. This is provided in Theorem 1. Let us denote (i) \(\mathcal{F}(T)\), the set of fringe nodes of a tree \(T\); (ii) \(e_T(b) = V^*(b) - L_T(b)\), the error function for node \(b\) in the tree \(T\); (iii) \(e(b) = V^*(b) - L(b)\), the error at a fringe node \(b \in \mathcal{F}(T)\); (iv) \(h_{b_0} b_{i+1}\), the unique action/observation sequence that leads from the root \(b_0\) to belief \(b\) in tree \(T\); (v) \(d(h)\), the depth of an action/observation sequence \(h\) (number of actions); and (vi) \(P(h|b_0, \pi^*) = \prod_{i=1}^{d(h)} P(h_i|b_{0-i}, h)\pi^*(b_{0-i}, h)\), the probability of executing the action/observation sequence \(h\) if we follow the optimal policy \(\pi^*\) from the root node \(b_0\) (where \(h_i\) and \(h)\) refers to the \(i^{th}\) action and observation in the sequence \(h\), and \(b_{0-i}\) is the belief obtained after taking the \(i\) first actions and observations from belief \(b\). \(\pi^*(b, a)\) is the probability that the optimal policy chooses action \(a\) in belief \(b\).

By abuse of notation, we will use \(b\) to represent both a belief node in the tree and its associated belief\footnote{e.g. \(\sum_{b \in \mathcal{F}(T)}\) should be interpreted as a sum over all fringe nodes in the tree, while \(e(b)\) to be the error associated to the belief in fringe node \(b\).}.
Theorem 1. In any tree $T$, $e_T(b_0) \leq \sum_{b \in \mathcal{F}(T)} \gamma^{d(b_0,b)} P(h_0^{b_0,b}|b_0, \pi^*) e(b)$. 

Proof. Consider an arbitrary parent node $b$ in tree $T$ and let’s denote $\hat{a}_b^* = \arg \max_{a \in A} L_T(b,a)$. We have $e_T(b) = V^*(b) - L_T(b)$. If $\hat{a}_b^* = \pi^*(b)$, then $e_T(b) = \gamma \sum_{a \in \Omega} P(a|b, \pi^*(b)) e_T(\tau(b, \pi^*(b), a))$. On the other hand, when $\hat{a}_b^* \neq \pi^*(b)$, then we know that $L_T(b, \pi^*(b)) \leq L_T(b, \hat{a}_b^*)$ and therefore $e_T(b) \leq \gamma \sum_{a \in \Omega} P(a|b, \pi^*(b)) e_T(\pi(b, \pi^*(b), a))$. Consequently, we have the following:

$$e_T(b) \leq \begin{cases} e(b) & \text{if } b \in \mathcal{F}(T) \\ \sum_{a \in \Omega} P(a|b, \pi^*(b)) e_T(\tau(b, \pi^*(b), a)) & \text{otherwise} \end{cases}$$

Then $e_T(b_0) \leq \sum_{b \in \mathcal{F}(T)} \gamma^{d(b_0,b)} P(h_0^{b_0,b}|b_0, \pi^*) e(b)$ can be easily shown by induction. \hfill \Box

4.1 Search Heuristics

From Theorem 1, we see that the contribution of each fringe node to the error in $b_0$ is simply the term $\gamma^{d(b_0,b)} P(h_0^{b_0,b}|b_0, \pi^*) e(b)$. Consequently, if we want to minimize $e_T(b_0)$ as quickly as possible, we should expand fringe nodes reached by the optimal policy $\pi^*$ that maximize the term $\gamma^{d(b_0,b)} P(h_0^{b_0,b}|b_0, \pi^*) e(b)$ as they offer the greatest potential to reduce $e_T(b_0)$. This suggests us a sound heuristic to explore the tree in a best-first-search way. Unfortunately we do not know $V^*$ nor $\pi^*$, which are required to compute the terms $e(b)$ and $P(h_0^{b_0,b}|b_0, \pi^*)$; nevertheless, we can approximate them. First, the term $e(b)$ can be estimated by the difference between the lower and upper bound. We define $\hat{e}(b) = U(b) - L(b)$ as an estimate of the error introduced by our bounds at fringe node $b$. Clearly, $\hat{e}(b) \geq e(b)$ since $U(b) \geq V^*(b)$.

To approximate $P(h_0^{b_0,b}|b_0, \pi^*)$, we can view the term $\pi^*(b,a)$ as the probability that action $a$ is optimal in belief $b$. Thus, we consider an approximate policy $\hat{\pi}_T$ that represents the probability that action $a$ is optimal in belief state $b$ given the bounds $L_T(b,a)$ and $U_T(b,a)$ that we have on $Q^*(b,a)$ in tree $T$. More precisely, to compute $\hat{\pi}_T(b,a)$, we consider $Q^*(b,a)$ as a random variable and make some assumptions about its underlying probability distribution. Once cumulative distribution functions $F_T^{b,a}$, s.t. $F_T^{b,a}(x) = P(Q^*(b,a) \leq x)$, and their associated density functions $f_T^{b,a}$ are determined for each $(b,a)$ in tree $T$, we can compute the probability $\hat{\pi}_T(b,a) = P(Q^*(b,a') \leq Q^*(b,a) \forall a' \neq a) = \int_{-\infty}^{\infty} f_T^{b,a}(x) \prod_{a' \neq a} F_T^{b,a'}(x) dx$. Computing this integral may not be computationally efficient depending on how we define the functions $f_T^{b,a}$. We consider two approximations.

One possible approximation is to simply compute the probability that the Q-value of a given action is higher than its parent belief state value (instead of all actions’ Q-value). In this case, we get $\hat{\pi}_T(b,a) = \int_{-\infty}^{\infty} f_T^{b,a}(x) F_T^{b}(x) dx$, where $F_T^{b}$ is the cumulative distribution function for $V^*(b)$, given bounds $L_T(b)$ and $U_T(b)$ in tree $T$. Hence by considering both $Q^*(b,a)$ and $V^*(b)$ as random variables with uniform distributions between their respective lower and upper bounds, we get:

$$\hat{\pi}_T(b,a) = \begin{cases} \frac{U_T(b,a) - L_T(b,a)}{U_T(b,a) - L_T(b,a)} & \text{if } U_T(b,a) > L_T(b,a), \\ 0 & \text{otherwise.} \end{cases}$$

(5)

where $\eta$ is a normalization constant such that $\sum_{a \in A} \hat{\pi}_T(b,a) = 1$. Notice that if the density function is 0 outside the interval between the lower and upper bound, then $\hat{\pi}_T(b,a) = 0$ for dominated actions, thus they are implicitly pruned from the search tree by this method.

A second practical approximation is:

$$\hat{\pi}_T(b,a) = \begin{cases} 1 & \text{if } a = \arg \max_{a' \in A} U_T(b,a') \\ 0 & \text{otherwise.} \end{cases}$$

(6)

which simply selects the action that maximizes the upper bound. This restricts exploration of the search tree to those fringe nodes that are reached by sequence of actions that maximize the upper bound of their parent belief state, as done in the $AO^*$ algorithm [14]. The nice property of this approximation is that these fringe nodes are the only nodes that can potentially reduce the upper bound in $b_0$. 
Using either of these two approximations for \( \hat{\pi}_T \), we can estimate the error contribution \( \hat{e}_T(b_0, b) \) of a fringe node \( b \) on the value of root belief \( b_0 \) in tree \( T \), as:

\[
\hat{e}_T(b_0, b) = \gamma d(b_0, b) P(h_T(b_0, b), \hat{\pi}_T) e(b).
\]

Using this as a heuristic, the next fringe node \( b(T) \) to expand in tree \( T \) is defined as:

\[
b(T) = \arg \max_{b \in F(T)} \gamma d(b_0, b) P(h_T(b_0, b), \hat{\pi}_T) e(b).
\]

We use AEMS\(^1\) to denote the heuristic that uses \( \hat{\pi}_T \) as defined in Equation 5, and AEMS\(^2\) to denote the heuristic that uses \( \hat{\pi}_T \) as defined in Equation 6.

### 4.2 Algorithm

Algorithm 1 presents the anytime error minimization search. Since the objective is to provide a near-optimal action within a finite allowed online planning time, the algorithm accepts two input parameters: \( t \), the online search time allowed per action, and \( \epsilon \), the desired precision on the value function.

**Algorithm 1 AEMS: Anytime Error Minimization Search**

Function \( \text{SEARCH}(t, \epsilon) \)

Static : \( T \): an AND-OR tree representing the current search tree.

\( t_o \leftarrow \text{TIME()} \)

while \( \text{TIME()} - t_o \leq t \) and not \( \text{SOLVED(Root}(T), \epsilon) \) do

\( b^* \leftarrow b(T) \)

\( \text{EXPAND}(b^*) \)

\( \text{UPDATEANCESTORS}(b^*) \)

end while

return \( \arg \max_{a \in A} LT(Root(T), a) \)

The \text{EXPAND} function expands the tree one level under the node \( b^* \) by adding the next action and belief nodes to the tree \( T \) and computing their lower and upper bounds according to Equations 1-4. After a node is expanded, the \text{UPDATEANCESTORS} function simply recomputes the bounds of its ancestors according to Equations determining \( b'(s'), V^*(b), P(o|b, a) \) and \( Q^*(b, a) \), as outlined in Section 2. It also recomputes the probabilities \( \hat{\pi}_T(b, a) \) and the best actions for each ancestor node. To find quickly the node that maximizes the heuristic in the whole tree, each node in the tree contains a reference to the best node to expand in their subtree. These references are updated by the \text{UPDATEANCESTORS} function without adding more complexity, such that when this function terminates, we always know immediately which node to expand next, as its reference is stored in the root node. The search terminates whenever there is no more time available, or we have found an \( \epsilon \)-optimal solution (verified by the \text{SOLVED} function). After an action is executed in the environment, the tree \( T \) is updated such that our new current belief state becomes the root of \( T \); all nodes under this new root can be reused at the next time step.

### 4.3 Completeness and Optimality

We now provide some sufficient conditions under which our heuristic search is guaranteed to converge to an \( \epsilon \)-optimal policy after a finite number of expansions. We show that the heuristics proposed in Section 4.1 satisfy those conditions, and therefore are admissible. Before we present the main theorems, we provide some useful preliminary lemmas.

**Lemma 1.** In any tree \( T \), the approximate error contribution \( \hat{e}_T(b_0, b_d) \) of a belief node \( b_d \) at depth \( d \) is bounded by \( \hat{e}_T(b_0, b_d) \leq \gamma^d \sup_b \hat{e}(b) \).

**Proof.** \( P(h_T(b_0, b), \hat{\pi}_T) \leq 1 \) and \( \hat{e}(b) \leq \sup_{b'} \hat{e}(b') \) for all \( b \). Thus \( \hat{e}_T(b_0, b_d) \leq \gamma^d \sup_b \hat{e}(b) \). \( \Box \)

For the following lemma and corollary, we will denote \( P(h_a|b_0, h_a) = \prod_{i=1}^{d(h)} P(h_i|b_0, h_{i-1}, h_i) \) the probability of observing the sequence of observations \( h_a \) in some action/observation sequence \( h \), given that the sequence of actions \( h_a \) in \( h \) is performed from current belief \( b_0 \), and \( \mathcal{F}(T) \subseteq \mathcal{F}(T) \) the set of all fringe nodes in \( T \) such that \( P(h_T(b_0, b), \hat{\pi}_T) > 0 \), for \( \hat{\pi}_T \) defined as in Equation 6 (i.e.

\(^1\)This heuristic is slightly different from the AEMS1 heuristic we had introduced in [11].

\(^2\)This is the same as the AEMS2 heuristic we had introduced in [11].
Corollary 2. For any tree $T$, $ε > 0$, and $D$ such that $γ^D \sup_b \hat{ε}(b) ≤ ε$, if for all $b ∈ \mathcal{F}(T)$, either $d(h_{T,b}^{0,b}) ≥ D$ or there exists an ancestor $b'$ of $b$ such that $\hat{ε}_T(b') ≤ ε$, then $\hat{ε}_T(b_0) ≤ ε$.

**Proof.** Let’s denote $\hat{a}_b^T = \arg\max_{a ∈ A} U_T(b, a)$. Notice that for any tree $T$, and parent belief $b ∈ T$, $\hat{ε}_T(b) = U_T(b) - L_T(b) ≤ U_T(b, \hat{a}_b^T) - L_T(b, \hat{a}_b^T) = γ \sum_{a ∈ Ω} P(a|b, \hat{a}_b^T) \hat{ε}_T(\tau(b, \hat{a}_b^T, o))$. Consequently, the following recurrence is an upper bound on $\hat{ε}_T(b)$:

$$\hat{ε}_T(b) ≤ \begin{cases} \hat{ε}(b) & \text{if } b ∈ \mathcal{F}(T) \\ ε \sum_{a ∈ Ω} P(a|b, \hat{a}_b^T) \hat{ε}_T(\tau(b, \hat{a}_b^T, o)) & \text{if } \hat{ε}_T(b) > ε \\ \text{otherwise} & \end{cases}$$

By unfolding the recurrence for $b_0$, we get $\hat{ε}_T(b_0) ≤ \sum_{b ∈ A(T)} γ \sum_{a ∈ Ω} P(a|b, \hat{a}_b^T) \hat{ε}_T(\tau(b, \hat{a}_b^T, o)) + ε \sum_{b' ∈ \mathcal{F}(T)} γ \sum_{a ∈ Ω} P(a|b', \hat{a}_{b'}^T) \hat{ε}_T(\tau(b', \hat{a}_{b'}^T, o))$

Theorem 2. For any tree $T$ and $ε > 0$, if $π_T$ is defined such that $\inf_{b, T[\hat{ε}_T(b) > ε]} \tilde{π}_T(b, \hat{a}_b^T) > 0$ for $\hat{a}_b^T = \arg\max_{a ∈ A} U_T(b, a)$, then Algorithm 1 using $\tilde{b}(T)$ is complete and $ε$-optimal.

**Proof.** If $γ = 0$, then the proof is immediate. Consider now the case where $γ ∈ (0, 1)$. Clearly, since $U$ is bounded above and $L$ is bounded below, then $\hat{ε}$ is bounded above. Now using $γ ∈ (0, 1)$, we can find a positive integer $D$ such that $γ^D \sup_b \hat{ε}(b) ≤ ε$. Let’s denote $\mathcal{A}_b^T$ the set of ancestor belief states of $b$ in the tree $T$, and given a finite set $A$ of belief nodes, let’s define $\hat{ε}^\text{min}_A(A) = \min_{b ∈ A} \hat{ε}_T(b)$. Now let’s define $T_0 = \{T|T \text{ finite}, b ∈ \mathcal{F}(T), \hat{ε}^\text{min}_A(A) > ε\}$ and $B = \{b|\hat{ε}(b) ∈ T_0\}$. Clearly, by the assumption that $\inf_{b, T[\hat{ε}_T(b) > ε]} \tilde{π}_T(b, \hat{a}_b^T) > 0$, then $B$ contains all belief states $b$ within depth $D$ such that $\hat{ε}(b) > D, P(h_{T,b}^{0,b}|b, h_{T,a}^{0,b}) > 0$ and there exists a finite tree $T$ where $b ∈ \mathcal{F}(T)$ and all ancestors $b'$ of $b$ have $\hat{ε}_T(b') > ε$. Furthermore, $B$ is finite since there are only finitely many belief states within depth $D$. Hence there exist an $E_{min} = \min_{b ∈ B} γ \sum_{a ∈ Ω} P(a|b, \hat{a}_b^T) \hat{ε}_T(\tau(b, \hat{a}_b^T, o))$. Clearly, $E_{min} > 0$ and we know that for any tree $T$, all beliefs $b ∈ B$ in $\mathcal{F}(T)$ have an approximate error contribution $\hat{ε}_T(b, a) ≥ E_{min}$. Since $E_{min} > 0$ and $γ ∈ (0, 1)$, there exist a positive integer $D'$ such that $γ^D \sup_b \hat{ε}(b) < E_{min}$. Hence by Lemma 1, this means that Algorithm 1 cannot expand any node at depth $D'$ or beyond before expanding a tree $T$ where $B ∈ \mathcal{F}(T) = ∅$. Because there are only finitely many nodes within depth $D'$, then it is clear that Algorithm 1 will reach such tree $T$ after a finite number of expansions. Furthermore, for this tree $T$, since $B ∈ \mathcal{F}(T) = ∅$, we have that for all beliefs $b ∈ \mathcal{F}(T)$, either $d(h_{T,b}^{0,b}) ≥ D$ or $E_{min}(A_b^T) ≤ ε$. Hence by Lemma 2, this implies that $\hat{ε}_T(b_0) ≤ ε$, and consequently Algorithm 1 will terminate after a finite number of expansions (Solved($b_0, ε$) will evaluate to true) with an $ε$-optimal solution (since $\hat{ε}_T(b_0) ≤ \hat{ε}_T(b_0)$).

From this last theorem, we notice that we can potentially develop many different admissible heuristics for Algorithm 1; the main sufficient condition being that $\tilde{π}_T(b, a) > 0$ for $a = \arg\max_{a ∈ A} U_T(\tilde{h}, a')$. It also follows from this theorem that the two heuristics described above, AEMS1 and AEMS2, are admissible. The following corollaries proves this:

**Corollary 1.** Algorithm 1, using $\tilde{b}(T)$, with $\tilde{π}_T$ as defined in Equation 6 is complete and $ε$-optimal.

**Proof.** Immediate by Theorem 2 and the fact that $\tilde{π}_T(b, \hat{a}_b^T) = 1$ for all $b, T$.

**Corollary 2.** Algorithm 1, using $\tilde{b}(T)$, with $\tilde{π}_T$ as defined in Equation 5 is complete and $ε$-optimal.

**Proof.** We first notice that $(U_T(b, a) - L_T(b))^2/(U_T(b, a) - L_T(b, a)) ≤ \hat{ε}(b, a)$, since $L_T(b) ≤ L_T(b, a)$ for all $a$. Furthermore, $\hat{ε}(b, a) ≤ \sup_b \hat{ε}(b')$. Therefore the normalization constant $η ≥ (|A| \sup_b \hat{ε}(b))^{-1}$. For $\hat{a}_b^T = \arg\max_{a ∈ A} U_T(b, a)$, we have $U_T(b, \hat{a}_b^T) = U_T(b)$, and therefore $U_T(b, \hat{a}_b^T) - L_T(b) = \hat{ε}(b)$. Hence this means that $\hat{π}_T(b, \hat{a}_b^T) = \eta(\hat{ε}_T(b))^2/\hat{ε}_T(b, \hat{a}_b^T) ≥$
5 Experiments

In this section we present a brief experimental evaluation of Algorithm 1, showing that in addition to its useful theoretical properties, the empirical performance matches, and in some cases exceeds, that of other online approaches. The algorithm is evaluated in three large POMDP environments: Tag [1], RockSample [3] and FieldVisionRockSample (FVRS) [11]; all are implemented using a factored state representation. In each environments we compute the Blind policy to get a lower bound and the FIB algorithm [15] to get an upper bound. We then compare performance of Algorithm 1 with both heuristics (AEMS1 and AEMS2) to the performance achieved by other online approaches (Satia [7], BI-POMDP [8], RTBSS [10]). For all approaches we impose a real-time constraint of 1 sec/action, and measure the following metrics: average return, average error bound reduction (Satia [7], BI-POMDP [8], RTBSS [10]). For all approaches we impose a real-time constraint of 1 sec/action, and measure the following metrics: average return, average error bound reduction (Satia [7], BI-POMDP [8], RTBSS [10]). For all approaches we impose a real-time constraint of 1 sec/action, and measure the following metrics: average return, average error bound reduction (Satia [7], BI-POMDP [8], RTBSS [10]). For all approaches we impose a real-time constraint of 1 sec/action, and measure the following metrics: average return, average error bound reduction (Satia [7], BI-POMDP [8], RTBSS [10]). \[
\frac{1}{|A|}(\sup_b \epsilon(b))^{-1}(\epsilon_T(b)) \text{ for all } T, b. \quad \text{Hence, for any } \epsilon > 0, \inf_{b,T|\epsilon_T(b) > \epsilon} \hat{\pi}_T(b, a_T^x) \geq \frac{1}{|A|}(\sup_b \epsilon(b))^{-1} \epsilon^2 > 0. \text{ Hence, corrolary follows from Theorem 2.} \]

6 Conclusion

In this paper we examined theoretical properties of online heuristic search algorithms for POMDPs. To this end, we described a general online search framework, and examined two admissible heuristics to guide the search. The first assumes that is distributed uniformly at random between the bounds (Heuristic AEMS1), the second favors an optimistic point of view, and assume the \( Q^x(b, a) \) is equal to the upper bound (Heuristic AEMS2). We provided a general theorem that shows that AEMS1 and AEMS2 are admissible and lead to complete and \( \epsilon \)-optimal algorithms. Our experimental work supports the theoretical analysis, showing that AEMS2 is able to outperform online approaches. Yet it is equally interesting to note that AEMS1 did not perform nearly as well. This highlights the fact that not all admissible heuristics are equally useful. Thus it will be interesting in the future to develop further guidelines and theoretical results describing which subclasses of heuristics are most appropriate.

\(^2\)The policy obtained by taking the combination of the \(|A|\) \( \alpha \)-vectors that each represents the value of a policy performing the same action in every belief state.

\(^3\)The error bound reduction is defined as \( 1 - \frac{L_T(b_0) - L_T(b_0)}{L_T(b_0) - L_T(b_0)} \), when the search process terminates on \( b_0 \)

\(^4\)The lower bound improvement is defined as \( L_T(b_0) - L(b_0) \), when the search process terminates on \( b_0 \)

\(^5\)For RTBSS, the maximum search depth under the 1sec time constraint is show in parenthesis.
