Abstract

We develop a new feedforward neural network representation of Lipschitz functions from \([0, \rho]^n\) into \([0, 1]\) based on the level sets of the function. We show that

\[
\frac{n\rho L}{2\varepsilon_r} + \frac{1}{\sqrt{2}\varepsilon_r} + \left(1 + \frac{n}{\sqrt{2}}\right) \left(\frac{\rho L}{4\varepsilon_r}\right)^n
\]

is an upper bound on the number of nodes needed to represent \(f\) to within uniform error \(\varepsilon_r\), where \(L\) is the Lipschitz constant. We also show that the number of bits needed to represent the weights in the network in order to achieve this approximation is given by

\[
O\left(\frac{n^2\rho L}{\sqrt{2}4^n\varepsilon_r} \left(\frac{\rho L}{\varepsilon_r}\right)^n\right).
\]

We compare this bound with the \(\varepsilon\)-entropy of the functional class under consideration.

1 INTRODUCTION

We are concerned with the problem of the number of nodes needed in a feedforward neural network in order to represent a function to within a specified accuracy. All results to date (e.g. [7, 10, 15]) have been in the form of existence theorems, stating that there does exist a neural network which achieves a certain accuracy of representation, but no indication is given of the number of nodes necessary in order to achieve this. The two techniques we use are the notion of \(\varepsilon\)-entropy (also known
Table 1: Hierarchy of theoretical problems to be solved.

### ABSTRACT

1. Determination of the general approximation properties of feedforward neural networks. (Non-constructive results of the form mentioned above [15].)
2. Explicit constructive approximation theorems for feedforward neural networks, indicating the number (or bounds on the number) of nodes needed to approximate a function from a given class to within a given accuracy. (This is the subject of the present paper. We are unaware of any other work along these lines apart from [6].)
3. Learning in general. That is, results on learning that are not dependent on the particular representation chosen. The exciting new results using the Vapnik-Chervonenkis dimension [4, 9] fit into this category, as do studies on the use of Shortest Description Length principles [2].
5. Specific algorithms for learning in a specific architecture [14].

### CONCRETE

as metric entropy) originally introduced by Kolmogorov [16] and a representation of a function in terms of its level sets, which was used by Arnold [1]. The place of the current paper with respect to other works in the literature can be judged from table 1.

We study the question of representing a function $f$ in the class $F_{L,C}^{(\rho_1, \ldots, \rho_n), n}$, which is the space of real valued functions defined on the $n$-dimensional closed interval $X_{i=1}^n [0, \rho_i]$ with a Lipschitz constant $L$ and bounded in absolute value by $C$. If $\rho_i = \rho$ for $i = 1, \ldots, n$, we denote the space $F_{L,C}^{\rho, n}$. The error measure we use is the uniform or sup metric:

$$\varepsilon = \sup_{x \in [0, \rho]^n} |\tilde{f}(x) - f(x)|,$$

where $\tilde{f}$ is the approximation of $f$.

### 2 $\varepsilon$-ENTROPY OF FUNCTIONAL CLASSES

The $\varepsilon$-entropy $H_\varepsilon$ gives an indication of the number of bits required to represent with accuracy $\varepsilon$ an arbitrary function $f$ in some functional class. It is defined as the logarithm to base 2 of the number of elements in the smallest $\varepsilon$-cover of the functional class. Kolmogorov [16] has proved that

$$H_\varepsilon (F_{L,C}^{\rho, n}) = B(n) \left( \frac{\rho L}{\varepsilon} \right)^n$$

where $B(n)$ is a constant which depends only on $n$. We use this result as a yardstick for our neural network representation. A more powerful result is [18, p. 86]:

\[ \ldots \]
Theorem 1 Let \( p \) be a non-negative integer and let \( \alpha \in (0, 1] \). Set \( s = p + \alpha \). Let \( F_{s,L,C(0)}^{p,n} \) denote the space of real functions \( f \) defined on \([0, p]^{n}\) all of whose partial derivatives of order \( p \) satisfy a Lipschitz condition with constant \( L \) and index \( \alpha \), and are such that
\[
\left| \frac{\partial^{k_1+k_2+\cdots+k_n} f(0)}{\partial x_1^{k_1} \partial x_2^{k_2} \cdots \partial x_n^{k_n}} \right| \leq C \quad \text{for} \quad \sum_{i=1}^{n} k_i \leq p.
\]
Then for sufficiently small \( \varepsilon \),
\[
A(s, n) \rho^n \left( \frac{L}{\varepsilon} \right)^{\frac{k}{2}} \leq H \left( F_{s,L,C(0)}^{p,n} \right) \leq B(s, n) \rho^n \left( \frac{L}{\varepsilon} \right)^{\frac{k}{2}},
\]
where \( A(s, n) \) and \( B(s, n) \) are positive constants depending only on \( s \) and \( n \).

We discuss the implication of this below.

3 A NEURAL NETWORK REPRESENTATION BASED ON LEVEL SETS

We develop a new neural network architecture for representing functions from \([0, p]^{n}\) onto \([0, 1]\) (the restriction of the range to \([0, 1]\) is just a convenience and can be easily dropped). The basic idea is to represent approximations \( \tilde{f} \) of the function \( f \) in terms of the level sets of \( f \) (see figure 1). Then neural networks are used to approximate the above sets \( \tilde{l}_\alpha(f) \) of \( f \), where \( \tilde{l}_\alpha(f) \overset{\Delta}{=} \{ x : f(x) \geq \alpha \} = \bigcup_{\beta \geq \alpha} l_\beta(f) \) and \( l_\alpha(f) \) is the \( \alpha \)th level set: \( l_\alpha(f) \overset{\Delta}{=} \{ x : f(x) = \alpha \} \). The approximations \( \tilde{l}_\alpha(f) \) can
be implemented using three layer neural nets with threshold logic neurons. These approximations are of the form

\[
\tilde{l}_\alpha(f) = \bigcup_{m=1}^{\Lambda_m} \bigcup_{j=1}^{n} \left( S(h_{U_j, \theta_j}^{\lambda_m}) \cap S(h_{-U_j, -\theta_j^{\lambda_m} + \psi_j^{\lambda_m}}) \right),
\]

where \( \psi_j^{\lambda_m} \) is the "width" in the \( j \)th dimension of the \( \lambda_m \)th rectangular part of the \( m \)th component (disjoint connected subset) \( e_m^{(\alpha)} \) of the \( \alpha \)th approximate above-set \( \tilde{l}_\alpha \). \( C_\alpha \) is the number of components of the above-set \( \tilde{l}_\alpha(f) \), \( \Lambda_m \) is the number of convex \( n \)-rectangles (parts) that are required to form an \( \varepsilon \)-cover for \( e_m^{(\alpha)}(f) \), \( U_j \triangleq (u_j^{(1)}, \ldots, u_j^{(n)}) \), \( u_j^{(m)} \) is the \( m \)th component (disjoint connected subset) \( C_{\alpha,j} \) of the \( i \)th approximate above-set \( e_{\alpha,j} \). \( \varepsilon \) is the \( \varepsilon \)-half-space defined by the hyperplane \( h_{w, \theta} \):

\[
S(h_{w, \theta}) = \{ x : h_{w, \theta}(x) \geq 0 \},
\]

where \( h_{w, \theta}(x) = w \cdot x - \theta \) and \( w = (w_1, \ldots, w_n) \).

The function \( f \) is then approximated by

\[
\tilde{f}_{X, \text{NN}}(x) = \frac{1}{2N} + \frac{1}{N} \sum_{i=1}^{N} 1_{l_{\alpha,i}}(x),
\]

where \( \alpha_i = \frac{i-1}{N}, i = 1, \ldots, N \) and \( 1_S \) is the indicator function of a set \( S \). The approximation \( \tilde{f}_{X, \text{NN}}(x) \) is then further approximated by implementing (5) using \( N \) 3-layer neural nets in parallel:

\[
f_{\text{NN}}(x) = \frac{1}{2N} + \sum_{i=1}^{N} s_{\alpha_i} \bigg( \bigwedge_{m=1}^{K_m^{(i)}} \bigg( \sum_{q=1}^{n} u_{k_m^{(i)}, q} x_q - \theta_{k_m^{(i)}} \bigg) \bigg) \quad x \in \times_{i=1}^{n} [0, \rho_i],
\]

where \( x = (x_1, \ldots, x_n)^T \), \( s_{\alpha_i} = \frac{1}{N} \) and \( n_{\alpha_i}^{(i)} \) is the number of nodes in the second layer. The last layer combines the above-sets in the manner of (7). The general architecture of the network is shown in figure 2.

### 4 NUMBER OF BITS NEEDED TO REPRESENT THE WEIGHTS OF THE NETWORK

The two main results of this paper are bounds on the number of nodes needed in such a neural network in order to represent \( f \in F_{\varepsilon}^{n} \) with uniform error \( \varepsilon \), and bounds on the number of bits needed to represent the weights in such an approximation.

**Theorem 2** The number of nodes needed in a neural network of the above architecture in order to represent any \( f \in F_{\varepsilon}^{n} \), to within \( \varepsilon \), in the sup-metric is given by

\[
\frac{n \rho L}{2 \varepsilon} + \frac{1}{\sqrt{2} \varepsilon} + \left( 1 + \frac{n}{\sqrt{2}} \right) \left( \frac{\rho L}{4 \varepsilon} \right)^n.
\]
This theorem is proved in a straightforward manner by taking account of all the errors incurred in the approximation of a worst-case function in $F_{L,C}^p$. Since comparing the number of nodes alone is inadequate for comparing the complexity of neural nets (because the nodes themselves could implement quite complex functions) we have also calculated the number of bits needed to represent all of the weights (including zero weights which denote no connection) in order to achieve an $\varepsilon_r$-approximation.¹

Theorem 3 The number of bits needed to specify the weights in a neural network with the above architecture in order to represent an arbitrary function $f \in F_{L,C}^{p,n}$ with accuracy $\varepsilon_r$ in the sup-metric is bounded above by

$$O \left( \frac{n^2 \rho L}{\sqrt{24^n \varepsilon_r}} \left( \frac{\rho L}{\varepsilon_r} \right)^n \right).$$

Equation 10 can be compared with (2) to see that the neural net representation is close to optimal. It is suboptimal by a factor of $O\left( \frac{\rho L}{\varepsilon_r} \right)$. The $\frac{n^2}{\sqrt{24^n}}$ term is considered subsumed into the $B(n)$ term in (2).

¹The idea of using the number of bits as a measure of network complexity has also recently been adopted in [5].
5 FURTHER WORK

Theorem 3 shows that the complexity of representing an arbitrary \( f \in F_{L_1,C}^{p,n} \) is exponential in \( n \). This is not so much a limitation of the neural network as an indication that our problem is too hard. Theorem 1 shows that if smoothness constraints are imposed, then the complexity can be considerably reduced. It is an open problem to determine whether the construction of the network presented in this paper can be extended to make good use of smoothness constraints.

Of course the most important question is whether functions can be learned using neural networks. Apropos of this is Stone's result on rates of convergence in non-parametric regression [17]. Although we do not have space to give details here, suffice it say that he shows that the gains suggested by theorem 1 by imposing smoothness constraints in the representation problem, are also achievable in the learning problem. A more general statement of this type of result, making explicit the connexion with \( \varepsilon \)-entropy is given by Yatracos [19]:

**Theorem 4** Let \( M \) be a \( L_1 \)-totally bounded set of measures on a probability space. Let the metric defined on the space be the \( L_1 \)-distance between measures. Then there exists a uniformly consistent estimator \( \hat{\theta}_i \) for some parameter \( \theta \) from a possibly infinite dimensional family of measures \( \Theta \subset M \) whose rate of convergence in \( i \) asymptotically satisfies the equation

\[
a_i = \left[ \frac{\mathcal{H}_i(\Theta)}{\varepsilon} \right]^{1/2}
\]

where \( \mathcal{H}_i(\Theta) \) is the \( \varepsilon \)-entropy of \( \Theta \).

Similar results have been discussed by Ben-David et al. [3] (who have made use of Dudley's (loose) relationships between \( \varepsilon \)-entropy and Vapnik-Chervonenkis dimension [8]) and others [12,13]. There remain many open problems in this field. One of the main difficulties however is the calculation of \( \mathcal{H}_e \) for non-trivial function classes. One of the most significant results would be a complete and tight determination of the \( \varepsilon \)-entropy for a feedforward neural network.
