Abstract

This paper introduces GNARL, an evolutionary program which induces recurrent neural networks that are structurally unconstrained. In contrast to constructive and destructive algorithms, GNARL employs a population of networks and uses a fitness function's unsupervised feedback to guide search through network space. Annealing is used in generating both gaussian weight changes and structural modifications. Applying GNARL to a complex search and collection task demonstrates that the system is capable of inducing networks with complex internal dynamics.

1 INTRODUCTION

A variety of methods to induce network architecture exist. Some start with a very simple network and incrementally add nodes and links (Hanson 1990; Fahlman & Lebiere, 1990; Fahlman 1991; Chen, et al., 1993); others start with a large network and then prune off superfluous pieces (Mozer & Smolensky, 1989; Cun, Denker, and Solla, 1990; Hassibi & Stork, 1993; Omlin & Giles, 1993). But these constructive and destructive algorithms are monotonic extremes that ignore a more moderate solution: "dynamically add or remove pieces of architecture as needed." Moreover, by exclusively exploring either feedforward networks (e.g., Ash, 1989), fully-connected recurrent networks (e.g., Chen, et al. 1993), or some restricted middle ground (e.g., Fahlman, 1991), these algorithms allow only limited structural change. Finally, constructive and destructive algorithms are supervised methods
which rely on complex predicates to determine when to add or delete pieces of network architecture (e.g., “when rate of improvement falls below threshold”).

Genetic algorithms (Holland 1975), on the other hand, are unsupervised methods which can induce networks by making stochastic modifications to a population of bitstrings, each of which is interpreted as a network. Most studies, however, still assume a fixed structure for the network (e.g., Belew et al., 1990; Jefferson, et al., 1991; see also Schaffer, et al. 1992), and those that do not allow only limited structural change (e.g., Potter, 1992, and Karunanithi et al., 1992).

Evolutionary programming (Fogel, 1992) is an alternate optimization technique which, when applied to network induction, obviates the need for a bitstring-to-network mapping by mutating networks directly. Furthermore, because EP does not employ crossover (an operator of questionable efficacy on distributed representations), it is a better candidate for inducing network structures (Angeline, Saunders, and Pollack, 1993; Fogel et al., 1990).

2 THE GNARL ALGORITHM

GNARL (GeNeralized Acquisition of Recurrent Links) is an evolutionary program that non-monotonically constructs recurrent networks to solve a given task. It begins with an initial population of $n$ random individuals; a sample network $N$ is shown in Figure 1. The number of input nodes ($num-in$) and number of output nodes ($num-out$) are fixed for a given task; the number of hidden nodes as well as the connections among them are free to vary. Self-links as well as general loops are allowed. Thus GNARL’s search space is $N \equiv \{N: \text{network } N \text{ has } num-in \text{ input nodes and } num-out \text{ output nodes}\}$.

In each epoch of search, the networks are ranked by a user-supplied fitness function $f: N \rightarrow \mathbb{R}$, where $\mathbb{R}$ represents the reals. Reproduction of the best $n/2$ individuals entails modifying both the weights and structure of each parent network $N$. First, the temperature $T(N)$ is calculated:

$$T(N) = 1 - \frac{f(N)}{f_{\text{max}}}$$  \hspace{1cm} (1)

where $f_{\text{max}}$ (provided by the user) is the maximum possible fitness for a given task. This
A measure of \( N \)'s performance is used to anneal the structural and parametric (Barto, 1990) similarity between parent and offspring, so that networks with a high temperature are mutated severely, and those with a low temperature are mutated only slightly. This allows a coarse-grained search initially, and a finer-grained search as a network approaches a solution (cf. Kirkpatrick et al., 1983).

More concretely, parametric mutations are accomplished by perturbing each weight with gaussian noise, whose variance is \( T(N)^2 \):

\[
w \leftarrow w + \text{Normal}(0; T(N)), \quad \forall w \in N
\]  

Structural mutations are accomplished by:

- adding \( k_1 \) hidden nodes with probability \( P_{\text{add-node}} \)
- deleting \( k_2 \) hidden nodes with probability \( P_{\text{delete-node}} \)
- adding \( k_3 \) links with probability \( P_{\text{add-link}} \)
- deleting \( k_4 \) links with probability \( P_{\text{delete-link}} \)

where each \( k_j \) is selected uniformly from a user-defined range, again annealed by \( T(N) \). When a node is added, it is initialized without connections; when a node is deleted, all its incident links are removed. All new links are initialized to 0. (See also Angeline, Saunders, and Pollack, 1993.)

3 RESULTS

GNARL was tested on a simple control task - the Tracker task of Jefferson, et al. (1991) and Koza (1992). In this problem, a simulated ant is placed on a two-dimensional toroidal grid and must maximize the number of pieces of food it collects in a given time period (Figure 2a). Each ant is controlled by a network with two input nodes and four output nodes (Figure 2b). At each step, the action whose corresponding output node has maximum activation is performed. Fitness is the number of grid positions cleared within 200 time steps.

The experiments used a population of 100 networks. In the first run (2090 generations), GNARL found a network (Figure 3b) that cleared 81 grid positions within the 200 time steps. Figure 4 shows the state of the output units of the network over three different sets of inputs. Each point is a triple of the form \( \text{move, right, left} \). (No-op is not shown because it was never used in the final network.) Figure 4a shows the result of supplying to the network 200 “food” inputs - a fixed point that executes “Move.” Figure 4b shows the sequence of states reached when 200 “no food” signals are supplied to the network - a collection of points describing a limit cycle of length 5 that repeatedly executes the sequence “Right, Right, Right, Right, Move.” These two attractors determine the response of the network to the task (Figure 4c,d); the additional points in Figure 4c are transients encountered as the network alternates between these attractors.

However, not all evolved network behaviors are so simple as to approximate an FSA (Pollack, 1991). In a second run (1595 generations) GNARL induced a network that cleared 82 grid points within the 200 time steps. Figure 5 demonstrates the behavior of this network. Once again, the “food” attractor, shown in Figure 5a, is a single point in the space that always executes “Move.” The “no food” behavior, however, is not an FSA; instead, it is a
Figure 2: The ant problem. (a) The trail is connected initially, but becomes progressively more difficult to follow. The underlying 2-d grid is toroidal, so that position “P” is the first break in the trail. The ellipse indicates the 7 pieces of food that the network of the second run failed to reach. (b) The semantics of the I/O units for the ant network. The first input node denotes the presence of food in the square directly in front of the ant; the second denotes the absence of food in this same square. No-op, from Jefferson, allows the network to stay in one position while activation flows through recurrent links. This particular network “eats” 42 pieces of food before spinning endlessly in place at position P, illustrating a very deep local minimum in the search space.

A quasiperiodic trajectory of points shaped like a “D” in output space (Figure 5b). The placement of the “D” is in the “Move / Right” corner of the space and encodes a complex alternation between these two operations (Figure 5d).

4 CONCLUSIONS

Artificial architectural constraints (such as “feedforwardness”) close the door on entire classes of behavior; forced liberties (such as assumed full recurrence) may unnecessarily increase structural complexity or learning time. By relying on a simple stochastic process, GNARL strikes a middle ground between these two, allowing the network’s complexity and behavior to emerge in response to the demands of the task.

Acknowledgments

The research reported in this paper has been partially supported by Office of Naval Research grants N00014-93-1-0059 and N00014-92-J-1195. We are indebted to all those who read and reviewed this work, especially John Kolen, Ed Large, and Barbara Becker.
Figure 3: The Tracker Task, first run. (a) The best network in the initial population. Nodes 0 & 1 are input, nodes 5-8 are output, and nodes 2-4 are hidden nodes. (b) Network induced by GNARL after 2090 generations. Forward links are dashed; bidirectional links & loops are solid. The light gray connection between nodes 8 and 13 is the sole backlink. This network clears the trail in 319 epochs. (c) Jefferson et al.'s fixed network structure for the Tracker task.
