Abstract

With substantial amount of time, resources and human (team) efforts invested to explore and develop successful deep neural networks (DNN), there emerges an urgent need to protect these inventions from being illegally copied, redistributed, or abused without respecting the intellectual properties of legitimate owners. Following recent progresses along this line, we investigate a number of watermark-based DNN ownership verification methods in the face of ambiguity attacks, which aim to cast doubts on the ownership verification by forging counterfeit watermarks. It is shown that ambiguity attacks pose serious threats to existing DNN watermarking methods. As remedies to the above-mentioned loophole, this paper proposes novel passport-based DNN ownership verification schemes which are both robust to network modifications and resilient to ambiguity attacks. The gist of embedding digital passports is to design and train DNN models in a way such that, the DNN inference performance of an original task will be significantly deteriorated due to forged passports. In other words, genuine passports are not only verified by looking for the predefined signatures, but also reasserted by the unyielding DNN model inference performances. Extensive experimental results justify the effectiveness of the proposed passport-based DNN ownership verification schemes. Code and models are available at https://github.com/kamwoh/DeepIPR

1 Introduction

With the rapid development of deep neural networks (DNN), Machine Learning as a Service (MLaaS) has emerged as a viable and lucrative business model. However, building a successful DNN is not a trivial task, which usually requires substantial investments on expertise, time and resources. As a result of this, there is an urgent need to protect invented DNN models from being illegally copied, redistributed or abused (i.e. intellectual property infringement). Recently, for instance, digital watermarking techniques have been adopted to provide such a protection, by embedding watermarks into DNN models during the training stage. Subsequently, ownerships of these inventions are verified by the detection of the embedded watermarks, which are supposed to be robust to multiple types of modifications such as model fine-tuning, model pruning and watermark overwriting [1–4].

In terms of deep learning methods to embed watermarks, existing approaches can be broadly categorized into two schools: a) the feature-based methods that embed designated watermarks into the DNN weights by imposing additional regularization terms [1, 3, 5]; and b) the trigger-set based methods that rely on adversarial training samples with specific labels (i.e. backdoor trigger sets) [2, 4]. Watermarks embedded with either of these methods have successfully demonstrated robustness...
(a) Application Scenario.  
(b) Present Solution.  
(c) Proposed Solution.

Figure 1: DNN model ownership verification in the face of ambiguity attacks. (a): Owner Alice uses an embedding process $E$ to train a DNN model with watermarks $(T, s)$ and releases the model publicly available; Attacker Bob forges counterfeit watermarks $(T', s')$ with an invert process $I$; (b): The ownership is in doubt since both the original and forged watermarks are detected by the verification process $V$ (Sect. 2.2); (c): The ambiguity is resolved when our proposed passports are embedded and the network performances are evaluated in favour of the original passport by the fidelity evaluation process $F$ (See Definition 1 and Sect. 3.3).

against removal attacks which involve modifications of the DNN weights such as fine-tuning or pruning. However, our studies disclose the existence and effectiveness of ambiguity attacks which aim to cast doubt on the ownership verification by forging additional watermarks for DNN models in question (see Fig. 1). We also show that it is always possible to reverse-engineer forged watermarks at minor computational cost where the original training dataset is also not needed (Sect. 2).

As remedies to the above-mentioned loophole, this paper proposes a novel passport-based approach. There is a unique advantage of the proposed passports over traditional watermarks - i.e. the inference performance of a pre-trained DNN model will either remain intact given the presence of valid passports, or be significantly deteriorated due to either the modified or forged passports. In other words, we propose to modulate the inference performances of the DNN model depending on the presented passports, and by doing so, one can develop ownership verification schemes that are both robust to removal attacks and resilient to ambiguity attacks at once (Sect. 3).

The contributions of our work are threefold: i) we put forth a general formulation of DNN ownership verification schemes and, empirically, we show that existing DNN watermarking methods are vulnerable to ambiguity attacks; ii) we propose novel passport-based verification schemes and demonstrate with extensive experiment results that these schemes successfully defeat ambiguity attacks; iii) methodology-wise, the proposed modulation of DNN inference performance based on the presented passports (Eq. 4) plays an indispensable role in bringing the DNN model behaviours under control against adversarial attacks.

1.1 Related work

Uchida et. al [1] was probably the first work that proposed to embed watermarks into DNN models by imposing an additional regularization term on the weights parameters. [2, 6] proposed to embed watermarks in the classification labels of adversarial examples in a trigger set, so that the watermarks can be extracted remotely through a service API without the need to access the network weights (i.e. black-box setting). Also in both black-box and white box settings, [3, 5, 7] demonstrated how to embed watermarks (or fingerprints) that are robust to various types of attacks. In particular, it was shown that embedded watermarks are in general robust to removal attacks that modify network weights via fine-tuning or pruning. Watermark overwriting, on the other hand, is more problematic since it aims to simultaneously embed a new watermark and destroy the existing one. Although [5] demonstrated robustness against overwriting attack, it did not resolve the ambiguity resulted from the counterfeit watermark. Adi et al. [2] also discussed how to deal with an adversary who fine-tuned an already watermarked networks with new trigger set images. Nevertheless, [2] required the new set of images to be distinguishable from the true trigger set images. This requirement is however often unfulfilled in practice, and our experiment results show that none of existing watermarking methods are able to deal with ambiguity attacks explored in this paper (see Sect. 2).

In the context of digital image watermarking, [8, 9] have studied ambiguity attacks that aim to create an ambiguous situation in which a watermark is reverse-engineered from an already watermarked image, by taking advantage of the invertibility of forged watermarks [10]. It was argued that robust watermarks do not necessarily imply the ability to establish ownership, unless non-invertible watermarking schemes are employed (see Proposition 2 for our proposed solution).
2 Rethinking Deep Neural Network Ownership Verification

This section analyses and generalizes existing DNN watermarking methods in the face of ambiguity attacks. We must emphasize that the analysis mainly focuses on three aspects i.e. fidelity, robustness and invertibility of the ownership verification schemes, and we refer readers to representative previous work [1][4] for formulations and other desired features of the entire watermark-based intellectual property (IP) protection schemes, which are out of the scope of this paper.

2.1 Reformulation of DNN ownership verification schemes

Figure[1] summarizes the application scenarios of DNN model ownership verifications provided by the watermark based schemes. Inspired by [10], we also illustrate an ambiguous situation in which rightful ownerships cannot be uniquely resolved by the current watermarking schemes alone. This loophole is largely due to an intrinsic weakness of the watermark-based methods i.e. invertibility. Formally, the definition of DNN model ownership verification schemes is generalized as follows.

Definition 1. A DNN model ownership verification scheme is a tuple $\mathcal{V} = (E, F, V, I)$ of processes:

I) An embedding process $E([D_t, T, s, N[\cdot], L] = N[W, T, s],)$ is a DNN learning process that takes training data $D_t = \{X_{t}, y_{t}\}$ as inputs, and optionally, either trigger set data $T = \{X_T, y_T\}$ or signature $s$, and outputs the model $N[W, T, s]$ by minimizing a given loss $L$.

Remark: the DNN architectures are pre-determined by $N[\cdot]$ and, after the DNN weights $W$ are learned, either the trigger set $T$ or signatures $s$ will be embedded and can be verified by the verification process defined next[7].

II) A fidelity evaluation process $F([N[W, \cdot, \cdot], D_t, M_t, \epsilon_f]) = \{True, False\}$ is to evaluate whether or not the discrepancy is less than a predefined threshold i.e. $|M([N[W, \cdot, \cdot], D_t]) - M_t| \leq \epsilon_f$, in which $M([N[W, \cdot, \cdot], D_t])$ is the DNN inference performance tested against a set of test data $D_t$, where $M_t$ is the target inference performance.

Remark: it is often expected that a well-behaved embedding process will not introduce a significant inference performance change that is greater than a predefined threshold $\epsilon_f$. Nevertheless, this fidelity condition remains to be verified for DNN models under either removal attacks or ambiguity attacks.

III) A verification process $V([N[W, \cdot, \cdot], T, s, \epsilon_s]) = \{True, False\}$ checks whether or not the expected signature $s$ or trigger set $T$ is successfully verified for a given DNN model $N[W, \cdot, \cdot]$.

Remark: for feature-based schemes, $V$ involves the detection of embedded signatures $s = \{P, B\}$ with a false detection rate that is lesser than a predefined threshold $\epsilon_s$. Specifically, the detection boils down to measure the distances $D_f(f_e(W, P), B)$ between target feature $B$ and features extracted by a transformation function $f_e(W, P)$ parameterized by $P$.

Remark: for trigger-set based schemes, $V$ first invokes a DNN inference process that takes trigger set samples $T_x$ as inputs, and then it checks whether the prediction $f(W, X_T)$ produces the designated labels $T_y$ with a false detection rate that is lesser than a threshold $\epsilon_s$.

IV) An invert process $I([N[W, T, s])] = N[W, T', s']$ exists and constitutes a successful ambiguity attack, if

(a) a set of new trigger set $T'$ and/or signature $s'$ can be reverse-engineered for a given DNN model;
(b) the forged $T', s'$ can be successfully verified with respect to the given DNN weights $W$ i.e. $V(I([N[W, T, s]]), T', s', \epsilon_s) = True$;
(c) the fidelity evaluation outcome $F([N[W, \cdot, \cdot], D_t, M_t, \epsilon_f])$ defined in Definition 1.II remains True.

Remark: this condition plays an indispensable role in designing the non-invertible verification schemes to defeat ambiguity attacks (see Sect. 3.3).

1Learning hyper-parameters such as learning rate and the type of optimization methods are considered irrelevant to ownership verifications, and thus they are not included in the formulation.

As proved by Proposition 1, one is able to construct forged watermarks for any already watermarked networks after and during DNN weights fine-tuning for transfer learning tasks. Top row denotes a DNN model trained with CIFAR10 and weights fine-tuned for CIFAR100; while bottom row denotes weight fine-tuned for Caltech-101. Accuracy outside bracket is the transferred task, while in-bracket is the original task. WM Det. denotes the detection accuracies of real and fake watermarks.

As proved by Proposition 1, one is able to construct forged watermarks for any already watermarked networks. We tested the performances of two representative DNN watermarking methods [1, 2], before and after DNN weights fine-tuning for transfer learning tasks. Top row denotes a DNN model trained with CIFAR10 and weights fine-tuned for CIFAR100; while bottom row denotes weight fine-tuned for Caltech-101. Accuracy outside bracket is the transferred task, while in-bracket is the original task. WM Det. denotes the detection accuracies of real and fake watermarks.

The definition as such is abstract and can be instantiated by concrete implementations of processes and functions. For instance, the following combined loss function (Eq. 1) generalizes loss functions adopted by both the feature-based and trigger-set based watermarking methods:

\[
L = L_c(f(W, X_r), y_r) + \lambda^1 L_c(f(W, X_T), y_T) + \lambda^r R(W, s),
\]

in which \(\lambda^1, \lambda^r\) are the relative weight hyper-parameters, \(f(W, X_r)\) are the network predictions with inputs \(X_r\) or \(X_T\). \(L_c\) is the loss function like cross-entropy that penalizes discrepancies between the predictions and the target labels \(y_r\) or \(y_T\). Signature \(s = \{P, B\}\) consists of passports \(P\) and signature string \(B\). The regularization terms could be either \(R = L_c(\sigma(W, P), B)\) as in [1] or \(R = MSE(B - PW)\) as in [2].

It must be noted that, for those DNN models that will be used for classification tasks, their inference performance \(\mathcal{M}(\{W[p, \cdot], D_t\}) = L_c(f(W, X_t), y_t)\) tested against a dataset \(D_t = \{X_t, y_t\}\) is independent of either the embedded signature \(s\) or trigger set \(T\). It is this independence that induces an invertible process for existing watermark-based methods as described next.

**Proposition 1 (Invertible process).** For a DNN ownership verification scheme \(\mathcal{V}\) as in Definition [1] if the fidelity process \(F()\) is independent of either the signature \(s\) or trigger set \(T\), then there always exists an invertible process \(I()\) i.e. the scheme is invertible \(\mathcal{V}^I = (E, F, V, I \neq \emptyset)\).

### 2.2 Watermarking in the face of ambiguity attacks

As proved by Proposition [1] one is able to construct forged watermarks for any already watermarked networks. We tested the performances of two representative DNN watermarking methods [1, 2], and Table [1] shows that counterfeit watermarks can be forged for the given DNN models with 100% detection rate, and 100% fake trigger set images can be reconstructed as well in the original task. Given that the detection accuracies for the forged trigger set is slightly better than the original trigger set after fine-tuning, the claim of the ownership is ambiguous and cannot be resolved by neither feature-based nor trigger-set based watermarking methods. Shockingly, the computational cost to forge counterfeit watermarks is quite minor where the forging required no more than 100 epochs to optimize, and worst still this is achieved without the need of original training data.

In summary, the ambiguity attacks against DNN watermarking methods are effective with minor computational and without the need of original training datasets. We ascribe this loophole to the crux that the loss of the original task, i.e. \(L_c(f(W, X_r), y_r)\) is independent of the forged watermarks. We refer readers to our extended version [11] for an elaboration on the ambiguity attack method we adopted and more detailed experiment results. In the next section, we shall illustrate a solution to defeat the ambiguity attacks.

### 3 Embedding passports for DNN ownership verification

The main motivation of embedding digital passports is to design and train DNN models in a way such that, their inference performances of the original task (i.e. classification accuracy) will be significantly deteriorated due to the forged signatures. We shall illustrate next first how to implement the desired property by incorporating the so called passport layers, followed by different ownership protection schemes that exploit the embedded passports to effectively defeat ambiguity attacks.
Figure 2: (a) Passport layers in ResNet architecture and (b) Classification accuracies modulated by different passports in CIFAR10, e.g. given counterfeit passports, the DNN models performance will be deteriorated instantaneously to fend off illegal usage.

### 3.1 Passport layers

In order to control the DNN model functionalities by the embedded digital signatures i.e. passports, we proposed to append after a convolution layer a passport layer, whose scale factor $\gamma$ and bias shift term $\beta$ are dependent on both the convolution kernels $W_p$ and the designated passport $P$ as follows:

$$
O^l(X_p) = \gamma^l X^l_p + \beta^l = \gamma^l(W^l_p \ast X^l_e) + \beta^l,
$$

$$
\gamma^l = \text{Avg}(W^l_p \ast P^l_\gamma),
\beta^l = \text{Avg}(W^l_p \ast P^l_\beta),
$$

in which $\ast$ denotes the convolution operations, $l$ is the layer number, $X_p$ is the input to the passport layer and $X_e$ is the input to the convolution layer. $O()$ is the corresponding linear transformation of outputs, while $P^l_\gamma$ and $P^l_\beta$ are the passports used to derive scale factor and bias term respectively. Fig. 2a delineates the architecture of digital passport layers used in a ResNet layer.

**Remark:** for DNN models trained with passport $s_c = \{P^l_\gamma, P^l_\beta\}^l$, their inference performances $M(\mathbb{N}[W, s_c], D_t, s_t)$ depend on the running time passports $s_t$ i.e.

$$
M(\mathbb{N}[W, s_c], D_t, s_t) = \begin{cases} 
M_{s_c}, & \text{if } s_t = s_c, \\
\overline{M}_{s_c}, & \text{otherwise}.
\end{cases}
$$

If the genuine passport is not presented $s_t \neq s_c$, the running time performance $\overline{M}_{s_c}$ is significantly deteriorated because the corresponding scale factor $\gamma$ and bias terms $\beta$ are calculated based on the wrong passports. For instance, as shown in Fig. 2b a proposed DNN model presented with valid passports (green) will demonstrate almost identical accuracies as to the original DNN model (red). In contrast, the same proposed DNN model presented with counterfeit passports (blue), the accuracy will deteriorate to merely about 10% only.

**Remark:** the gist of the proposed passport layer is to enforce dependence between scale factor, bias terms and network weights. As shown by the Proposition 2 it is this dependence that validates the required non-invertibility to defeat ambiguity.

**Proposition 2 (Non-invertible process).** A DNN ownership verification scheme $V$ as in Definition 1 is non-invertible, if

I) the fidelity process outcome $F(\mathbb{N}[W, T, s], D_t, M_t, \epsilon_f)$ depends either on the presented signature $s$ or trigger set $T$,

II) with forged passport $s_t \neq s_c$, the DNN inference performance $M(\mathbb{N}[W, s_c], D_t, s_t)$ in (Eq. 4) will deteriorate such that the discrepancy is larger than a threshold i.e. $|M_{s_c} - \overline{M}_{s_c}| > \epsilon_f$. 

5
3.2 Sign of scale factors as signature

During learning the DNN, to further protect the DNN models ownership from insider threat (e.g. a former staff who establish a new start-up business with all the resources stolen from originator), one can enforce the scale factor $\gamma$ to take either positive or negative signs ($\pm$) as designated, so that it will form a unique signature string (like fingerprint). This process is done by adding the following sign loss regularization term into the combined loss (Eq. 1):

$$R(\gamma, P, B) = \sum_{i=1}^{C} \max(\gamma_0 - \gamma_i b_i, 0)$$  (5)

in which $B = \{b_1, \ldots, b_C\} \in \{-1, 1\}^C$ consists of the designated binary bits for $C$ convolution kernels, and $\gamma_0$ is a positive control parameter (0.1 by default unless stated otherwise) to encourage the scale factors have magnitudes greater than $\gamma_0$.

It must be highlighted that the inclusion of sign loss (Eq. 5) enforces the scale factors $\gamma$ to take either positive or negative values, and the signs enforced in this way remain rather persistent against various adversarial attacks. This feature explains the superior robustness of embedded passports against ambiguity attacks by reverse-engineering shown in Sect. 4.2.

3.3 Ownership verification with passports

Taking advantages of the proposed passport-based approach, we design three new ownership verification schemes $V$ that are summarized next and refer readers to Sect. 4 for the experiment results.

$V_1$: Passport is distributed with the trained DNN model

Hereby, the learning process aims to minimize the combined loss function (Eq. 1), in which $\lambda_t = 0$ since trigger set images are not used in this scheme and the sign loss (Eq. 5) is added as the regularization term. The trained DNN model together with the passport are then distributed to legitimate users, who perform network inferences with the given passport fed to the passport layers as shown in Fig. 2a. The network ownership is automatically verified by the distributed passports. As shown in Table 2 and Fig. 3, this ownership verification is robust to DNN model modifications. Also, as shown in Fig. 4, ambiguity attacks are not able to forge a set of passport and signature that can maintain the DNN inference performance.

The downside of this scheme is the requirement to use passports during inferencing, which leads to extra computational cost by about 10% (see Sect. 4.3). Also the distribution of passports to the end-users is intrusive and imposes additional responsibility of guarding the passports safely.

$V_2$: Private passport is embedded but not distributed

Herein, the learning process aims to simultaneously achieve two goals, of which the first is to minimize the original task loss (e.g. classification accuracy discrepancy) when no passport layers included; and the second is to minimize the combined loss function (Eq. 1) with passports regularization included. Algorithm-wise, this multi-task learning is achieved by alternating between the minimization of these two goals. The successfully trained DNN model is then distributed to end-users, who may perform network inferencing without the need of passports. Note that this is possible since passport layers are not included in the distributed networks. The ownership verification will be carried out only upon requested by the law enforcement, by adding the passport layers to the network in question and detecting the embedded sign signatures with unyielding the original network inference performances.

Compared with scheme $V_1$, this scheme is easy to use for end-users since no passport is needed and no extra computational cost is incurred. In the meantime, this ownership verification is robust to removal attacks as well as ambiguity attacks. The downside, however, is the requirement to access the DNN weights and to append the passport layers for ownership verification, i.e. the disadvantages of white-box protection mode as discussed in [2]. Therefore, we propose to combine it with trigger-set based verification that will be described next.

$V_3$: Both the private passport and trigger set are embedded but not distributed

This scheme only differs from scheme $V_2$ in that, a set of trigger images is embedded in addition to the embedded passports. The advantage of this, as discussed in [2] is to probe and claim ownership
The aim of model pruning is to reduce redundant parameters without compromising the performance. Here, we adopt the class-blind pruning scheme in [14], and test our proposed DNN models with different pruning rates. Figure shows that, in general, our proposed DNN models still maintained near to 100% accuracy even 60% parameters are pruned, while the accuracy of testing data drops around 5%-25%. Even if we prune 90% parameters, the accuracy of our proposed DNN models are still much higher than the accuracy of testing data. As said, we ascribe the robustness against model pruning to the superior persistence of signatures embedded in the scale factor signs (see Sect. 3.2).

---

4 Experiment results

This section illustrates the experiment results of passport-based DNN models whereas the inference performances of various schemes are compared in terms of robustness to both removal attacks and ambiguity attacks. The network architectures we investigated include the well-known AlexNet and ResNet-18, which are tested with typical CIFAR10 and CIFAR100 classification tasks. These medium-sized public datasets allow us to perform extensive tests of the DNN model performances. Unless stated otherwise, all experiments are repeated 5 times and tested against 50 fake passports to get the mean inference performance. Also, to avoid confusion to the original AlexNet and ResNet models, we denote AlexNetp and ResNetp-18 as our proposed passport-based DNN models.

4.1 Robustness against removal attacks

Fine-tuning

Table 2 shows that the signatures are detected at near to 100% accuracy for all the ownership verification schemes in the original task. Even after fine-tuning the proposed DNN models for a new task (e.g. from CIFAR10 to Caltech-101), almost 100% accuracy are still maintained. Note that a detected signature is claimed only iff all the binary bits are exactly matched. We ascribe this superior robustness to the unique controlling nature of the scale factors — in case that a scale factor value is reduced near to zero, the channel output will be virtually zero, thus, its gradient will vanish and lose momentum to move towards to the opposite value. Empirically we have not observed counter-examples against this explanation.

Model pruning

The aim of model pruning is to reduce redundant parameters without compromising the performance. Here, we adopt the class-blind pruning scheme in [14], and test our proposed DNN models with different pruning rates. Figure 4 shows that, in general, our proposed DNN models still maintained near to 100% accuracy even 60% parameters are pruned, while the accuracy of testing data drops around 5%-25%. Even if we prune 90% parameters, the accuracy of our proposed DNN models are still much higher than the accuracy of testing data. As said, we ascribe the robustness against model pruning to the superior persistence of signatures embedded in the scale factor signs (see Sect. 3.2).

---

2 A rigorous proof of this argument is under investigation and will be reported elsewhere.
resilience against ambiguity attacks

As shown in Fig. 4, the accuracy of our proposed DNN models trained on CIFAR10/100 classification task is significantly depending on the presence of either valid or counterfeit passports — the proposed DNN models presented with valid passports demonstrated almost identical accuracies as to the original DNN model. Contrary, the same proposed DNN model presented with invalid passports (in this case of $fake_1 =$ random attack) achieved only 10% accuracy which is merely equivalent to a random guessing. In the case of $fake_2$, we assume that the adversaries have access to the original training dataset, and attempt to reverse-engineer the scale factor and bias term by freezing the trained DNN weights. It is shown that in Fig. 4 reverse-engineering attacks are only able to achieve, for CIFAR10, at best 84% accuracy on AlexNet and 70% accuracy on ResNet-18. While in CIFAR100, for $fake_1$ case, attack on both our proposed DNN models achieved only 1% accuracy; for $fake_2$ case, this attack only able to achieve 44% accuracy for AlexNet and 35% accuracy for ResNet-18.

Table 3 summarizes the accuracy of the proposed methods under three ambiguity attack modes, $fake$.

4.2 Resilience against ambiguity attacks

Based on these empirical studies, we decide to set the threshold $\epsilon_f$ in Definition 1 as 3% for AlexNet and 20% for ResNet-18, respectively. By this fidelity evaluation process, any potential ambiguity
We believe the proposed modulation of DNN performance based on the presented passports will play an indispensable role in bringing DNN behaviours under control against adversarial attacks, as it has been demonstrated for DNN ownership verifications. Nonetheless, we tested a larger network (i.e. ResNet-50) and its training time increases 10%, 182% and 191% respectively for \( V_1 \), \( V_2 \) and \( V_3 \) schemes. This increase is consistent with those smaller models i.e. AlexNet\(_p\) and ResNet\(_p\)-18.

### 4.3 Network Complexity

Table 4 summarizes the complexity of passport networks in various schemes. We believe that it is the computational cost at the inference stage that is required to be minimized, since network inference is going to be performed frequently by the end users. While extra costs at the training and verification stages, on the other hand, are not prohibitive since they are performed by the network owners, with the motivation to protect the DNN model ownerships. Nonetheless, we tested a larger network (i.e. ResNet\(_p\)-50) and its training time increases 10%, 182% and 191% respectively for \( V_1 \), \( V_2 \) and \( V_3 \) schemes. This increase is consistent with those smaller models i.e. AlexNet\(_p\) and ResNet\(_p\)-18.

### 5 Discussions and conclusions

Considering billions of dollars have been invested by giant and start-up companies to explore new DNN models virtually every second, we believe it is imperative to protect these inventions from being stolen. While ownership of DNN models might be resolved by registering the models with a centralized authority, it has been recognized that these regulations are inadequate and technical solutions are urgently needed to support the law enforcement and judicial protections. It is this motivation that highlights the unique contribution of the proposed method in unambiguous verification of DNN models ownerships.

Methodology-wise, our empirical studies re-asserted that over-parameterized DNN models can successfully learn multiple tasks with arbitrarily assigned labels and/or constraints. While this assertion has been theoretically proved [15] and empirically investigated from the perspective of network generalization [16], its implications to network security in general remain to be explored. We believe the proposed modulation of DNN performance based on the presented passports will play an indispensable role in bringing DNN behaviours under control against adversarial attacks, as it has been demonstrated for DNN ownership verifications.
