## Abstract

Many species show avoidance reactions in response to looming object approaches. In locusts, the corresponding escape behavior correlates with the activity of the lobula giant movement detector (LGMD) neuron. During an object approach, its firing rate was reported to gradually increase until a peak is reached, and then it declines quickly. The  $\eta$ -function predicts that the LGMD activity is a product between an exponential function of angular size  $\exp(-\Theta)$  and angular velocity  $\dot{\Theta}$ , and that peak activity is reached before time-to-contact (ttc). The  $\eta$ -function has become the prevailing LGMD model because it reproduces many experimental observations, and even experimental evidence for the multiplicative operation was reported. Several inconsistencies remain unresolved, though. Here we address these issues with a new model ( $\psi$ -model), which explicitly connects  $\Theta$  and  $\dot{\Theta}$  to biophysical quantities. The  $\psi$ -model avoids biophysical problems associated with implementing  $\exp(\cdot)$ , implements the multiplicative operation of  $\eta$  via divisive inhibition, and explains why activity peaks could occur after ttc. It consistently predicts response features of the LGMD, and provides excellent fits to published experimental data, with goodness of fit measures comparable to corresponding fits with the  $\eta$ -function.

## 1 Introduction: $\tau$ and $\eta$

Collision sensitive neurons were reported in species such different as monkeys [5, 4], pigeons [36, 34], frogs [16, 20], and insects [33, 26, 27, 10, 38]. This indicates a high ecological relevance, and raises the question about how neurons compute a signal that eventually triggers corresponding movement patterns (e.g. escape behavior or interceptive actions). Here, we will focus on visual stimulation. Consider, for simplicity, a circular object (diameter  $2l$ ), which approaches the eye at a collision course with constant velocity  $v$ . If we do not have any *a priori* knowledge about the object in question (e.g. its typical size or speed), then we will be able to access only two information sources. These information sources can be measured at the retina and are called optical variables (OVs). The first is the visual angle  $\Theta$ , which can be derived from the number of stimulated photoreceptors (spatial contrast). The second is its rate of change  $d\Theta(t)/dt \equiv \dot{\Theta}(t)$ . Angular velocity  $\dot{\Theta}$  is related to temporal contrast.

How should we combine  $\Theta$  and  $\dot{\Theta}$  in order to track an imminent collision? The perhaps simplest combination is  $\tau(t) \equiv \Theta(t)/\dot{\Theta}(t)$  [13, 18]. If the object hit us at time  $t_c$ , then  $\tau(t) \approx t_c - t$  will

give us a running estimation of the time that is left until contact<sup>1</sup>. Moreover, we do not need to know anything about the approaching object: The ttc estimation computed by  $\tau$  is practically independent of object size and velocity. Neurons with  $\tau$ -like responses were indeed identified in the nucleus retundus of the pigeon brain [34]. In humans, only fast interceptive actions seem to rely exclusively on  $\tau$  [37, 35]. Accurate ttc estimation, however, seems to involve further mechanisms (rate of disparity change [31]).

Another function of OV's with biological relevance is  $\eta \equiv \dot{\Theta} \exp(-\alpha\Theta)$ , with  $\alpha = \text{const.}$  [10]. While  $\eta$ -type neurons were found again in pigeons [34] and bullfrogs [20], most data were gathered from the LGMD<sup>2</sup> in locusts (e.g. [10, 9, 7, 23]). The  $\eta$ -function is a phenomenological model for the LGMD, and implies three principal hypothesis: (i) An implementation of an exponential function  $\exp(\cdot)$ . Exponentiation is thought to take place in the LGMD axon, via active membrane conductances [8]. Experimental data, though, seem to favor a third-power law rather than  $\exp(\cdot)$ . (ii) The LGMD carries out biophysical computations for implementing the multiplicative operation. It has been suggested that multiplication is done within the LGMD itself, by subtracting the logarithmically encoded variables  $\log \dot{\Theta} - \alpha\Theta$  [10, 8]. (iii) The peak of the  $\eta$ -function occurs before ttc, at visual angle  $\Theta(\hat{t}) = 2 \arctan(1/\alpha)$  [9]. It follows ttc for certain stimulus configurations (e.g.  $l/|v| \lesssim 5\text{ms}$ ). In principle,  $\hat{t} > t_c$  can be accounted for by  $\eta(t + \delta)$  with a fixed delay  $\delta < 0$  (e.g.  $-27\text{ms}$ ). But other researchers observed that LGMD activity continuous to rise after ttc even for  $l/|v| \gtrsim 5\text{ms}$  [28]. These discrepancies remain unexplained so far [29], but stimulation dynamics perhaps plays a role.

We will address these three issues by comparing the novel function “ $\psi$ ” with the  $\eta$ -function.

## 2 LGMD computations with the $\psi$ -function: No multiplication, no exponentiation

A circular object which starts its approach at distance  $x_0$  and with speed  $v$  projects a visual angle  $\Theta(t) = 2 \arctan[l/(x_0 - vt)]$  on the retina [34, 9]. The kinematics is hence entirely specified by the half-size-to-velocity ratio  $l/|v|$ , and  $x_0$ . Furthermore,  $\dot{\Theta}(t) = 2lv/((x_0 - vt)^2 + l^2)$ . In order to define  $\psi$ , we consider at first the LGMD neuron as an RC-circuit with membrane potential<sup>3</sup>  $V$  [17]

$$C_m \frac{dV}{dt} = \beta (V_{rest} - V) + g_{exc} (V_{exc} - V) + g_{inh} (V_{inh} - V) \quad (1)$$

$C_m$  = membrane capacity<sup>4</sup>;  $\beta \equiv 1/R_m$  denotes leakage conductance across the cell membrane ( $R_m$ : membrane resistance);  $g_{exc}$  and  $g_{inh}$  are excitatory and inhibitory inputs. Each conductance  $g_i$  ( $i = exc, inh$ ) can drive the membrane potential to its associated reversal potential  $V_i$  (usually  $V_{inh} \leq V_{exc}$ ). Shunting inhibition means  $V_{inh} = V_{rest}$ . Shunting inhibition lurks “silently” because it gets effective only if the neuron is driven away from its resting potential. With synaptic input, the neuron decays into its equilibrium state

$$V_\infty \equiv \frac{V_{rest}\beta + V_{exc}g_{exc} + V_{inh}g_{inh}}{\beta + g_{exc} + g_{inh}} \quad (2)$$

according to  $V(t) = V_\infty(1 - \exp(-t/\tau_m))$ . Without external input,  $V(t \gg 1) \rightarrow V_{rest}$ . The time scale is set by  $\tau_m$ . Without synaptic input  $\tau_m \equiv C_m/\beta$ . Slowly varying inputs  $g_{exc}, g_{inh} > 0$  modify the time scale to approximately  $\tau_m/(1 + (g_{exc} + g_{inh})/\beta)$ . For highly dynamic inputs, such as in late phase of the object approach, the time scale gets dynamical as well. The  $\psi$ -model assigns synaptic inputs<sup>5</sup>

$$g_{exc}(t) = \dot{\vartheta}(t), \quad \dot{\vartheta}(t) = \zeta_1 \dot{\vartheta}(t - \Delta t_{stim}) + (1 - \zeta_1) \dot{\Theta}(t) \quad (3a)$$

$$g_{inh}(t) = [\gamma \vartheta(t)]^e, \quad \vartheta(t) = \zeta_0 \vartheta(t - \Delta t_{stim}) + (1 - \zeta_0) \Theta(t) \quad (3b)$$

<sup>1</sup>This linear approximation gets worse with increasing  $\Theta$ , but turns out to work well until short before ttc ( $\tau$  adopts a minimum at  $t_c - 0.428978 \cdot l/|v|$ ).

<sup>2</sup>LGMD activity is usually monitored via its postsynaptic neuron, the Descending Contralateral Movement Detector (DCMD) neuron. This represents no problem as LGMD spikes follow DCMD spikes 1:1 under visual stimulation [22] from 300Hz [21] to at least 400Hz [24].

<sup>3</sup>Here we assume that the membrane potential serves as a predictor for the LGMD's mean firing rate.

<sup>4</sup>Set to unity for all simulations.

<sup>5</sup>LGMD receives also inhibition from a laterally acting network [21]. The  $\eta$ -function considers only direct feedforward inhibition [22, 6], and so do we.

Figure 1: (a) The continuous visual angle of an approaching object is shown along with its discretized version. Discretization transforms angular velocity from a continuous variable into a series of “spikes” (rescaled). (b) The  $\psi$  function with the inputs shown in a, with  $n_{relax} = 25$  relaxation time steps. Its peak occurs  $t_{max} = 56\text{ms}$  before  $t_c$  ( $t_c = 300\text{ms}$ ). An  $\eta$  function ( $\alpha = 3.29$ ) that was fitted to  $\psi$  shows good agreement. For continuous optical variables, the peak would occur 4ms earlier, and  $\eta$  would have  $\alpha = 4.44$  with  $R^2 = 1$ . For  $n_{relax} = 10$ ,  $\psi$  is farther away from its equilibrium at  $V_\infty$ , and its peak moves 19ms closer to  $t_c$ .

Figure 2: The figures plot the relative time  $t_{max} \equiv t_c - \hat{t}$  of the response peak of  $\psi$ ,  $V(\hat{t})$ , as a function of half-size-to-velocity ratio (points). Line fits with slope  $\alpha$  and intercept  $\delta$  were added (lines). The predicted linear relationship in all cases is consistent with experimental evidence [9]. (a) The stimulus time scale is held constant at  $\Delta t_{stim} = 1\text{ms}$ , and several LGMD time scales are defined by  $n_{relax}$  (= number of intercalated relaxation steps for each integration time step). Bigger values of  $n_{relax}$  move  $V(t)$  closer to its equilibrium  $V_\infty(t)$ , implying higher slopes  $\alpha$  in turn. (b) LGMD time scale is fixed at  $n_{relax} = 25$ , and  $\Delta t_{stim}$  is manipulated. Because of the discretization of optical variables (OVs) in our simulation, increasing  $\Delta t_{stim}$  translates to an overall smaller number of jumps in OVs, but each with higher amplitude.

Thus, we say  $\psi(t) \equiv V(t)$  if and only if  $g_{exc}$  and  $g_{inh}$  are defined with the last equation. The time scale of stimulation is defined by  $\Delta t_{stim}$  (by default 1ms). The variables  $\vartheta$  and  $\dot{\vartheta}$  are lowpass filtered angular size and rate of expansion, respectively. The amount of filtering is defined by memory constants  $\zeta_0$  and  $\zeta_1$  (no filtering if zero). The idea is to continue with generating synaptic input after  $t_c$ , where  $\Theta(t > t_c) = const$  and thus  $\dot{\Theta}(t > t_c) = 0$ . Inhibition is first weighted by  $\gamma$ , and then potentiated by the exponent  $e$ . Hodgkin-Huxley potentiates gating variables  $n, m \in [0, 1]$  instead (potassium  $\propto n^4$ , sodium  $\propto m^3$ , [12]) and multiplies them with conductances. Gabbiani and co-workers found that the function which transforms membrane potential to firing rate is better described by a power function with  $e = 3$  than by  $\exp(\cdot)$  (Figure 4d in [8]).

### 3 Dynamics of the $\psi$ -function

**Discretization.** In a typical experiment, a monitor is placed a short distance away from the insect’s eye, and an approaching object is displayed. Computer screens have a fixed spatial resolution, and as a consequence size increments of the displayed object proceed in discrete jumps. The locust retina is furthermore composed of a discrete array of ommatidia units. We therefore can expect a corresponding step-wise increment of  $\Theta$  with time, although optical and neuronal filtering may smooth  $\Theta$  to some extent again, resulting in  $\vartheta$  (figure 1). Discretization renders  $\dot{\Theta}$  discontinuous, what again will be alleviated in  $\dot{\vartheta}$ . For simulating the dynamics of  $\psi$ , we discretized angular size with  $\text{floor}(\Theta)$ , and  $\dot{\Theta}(t) \approx [\Theta(t + \Delta t_{stim}) - \Theta(t)]/\Delta t_{stim}$ . Discretized optical variables (OVs) were re-normalized to match the range of original (i.e. continuous) OVs.

**To peak, or not to peak?** Rind & Simmons reject the hypothesis that the activity peak signals impending collision on grounds of two arguments [28]: (i) If  $\Theta(t + \Delta t_{stim}) - \Theta(t) \gtrsim 3^\circ$  in consecutively displayed stimulus frames, the illusion of an object approach would be lost. Such stimulation would rather be perceived as a sequence of rapidly appearing (but static) objects, causing reduced responses. (ii) After the last stimulation frame has been displayed (that is  $\Theta = \text{const}$ ), LGMD responses keep on building up beyond ttc. This behavior clearly depends on  $l/|v|$ , also according to their own data (e.g. Figure 4 in [26]): Response build up after ttc is typically observed for sufficiently small values of  $l/|v|$ . Input into  $\psi$  in situations where  $\Theta = \text{const}$  and  $\dot{\Theta} = 0$ , respectively, is accommodated by  $\vartheta$  and  $\dot{\vartheta}$ , respectively.

We simulated (i) by setting  $\Delta t_{stim} = 5\text{ms}$ , thus producing larger and more infrequent jumps in discrete OVs than with  $\Delta t_{stim} = 1\text{ms}$  (default). As a consequence,  $\vartheta(t)$  grows more slowly (delayed build up of inhibition), and the peak occurs later ( $t_{max} \equiv t_c - \hat{t} = 10\text{ms}$  with everything else identical with figure 1b). The peak amplitude  $\hat{V} = V(\hat{t})$  decreases nearly sixfold with respect to default. Our model thus predicts the reduced responses observed by Rind & Simmons [28].

**Linearity.** Time of peak firing rate is linearly related to  $l/|v|$  [10, 9]. The  $\eta$ -function is consistent with this experimental evidence:  $\hat{t} = t_c - \alpha l/|v| + \delta$  (e.g.  $\alpha = 4.7$ ,  $\delta = -27\text{ms}$ ). The  $\psi$ -function reproduces this relationship as well (figure 2), where  $\alpha$  depends critically on the time scale of biophysical processes in the LGMD. We studied the impact of this time scale by choosing  $10\mu\text{s}$  for the numerical integration of equation 1 (algorithm: 4th order Runge-Kutta). Apart from improving the numerical stability of the integration algorithm,  $\psi$  is far from its equilibrium  $V_\infty(t)$  in every moment  $t$ , given the stimulation time scale  $\Delta t_{stim} = 1\text{ms}$ <sup>6</sup>. Now, at each value of  $\Theta(t)$  and  $\dot{\Theta}(t)$ , respectively, we intercalated  $n_{relax}$  iterations for integrating  $\psi$ . Each iteration takes  $V(t)$  asymptotically closer to  $V_\infty(t)$ , and  $\lim_{n_{relax} \gg 1} V(t) = V_\infty(t)$ . If the internal processes in the LGMD cannot keep up with stimulation ( $n_{relax} = 0$ ), we obtain slopes values that underestimate experimentally found values (figure 2a). In contrast, for  $n_{relax} \gtrsim 25$  we get an excellent agreement with the experimentally determined  $\alpha$ . This means that – under the reported experimental stimulation conditions (e.g. [9]) – the LGMD would operate relatively close to its steady state<sup>7</sup>.

Now we fix  $n_{relax}$  at 25 and manipulate  $\Delta t_{stim}$  instead (figure 2b). The default value  $\Delta t_{stim} = 1\text{ms}$  corresponds to  $\alpha = 3.91$ . Slightly bigger values of  $\Delta t_{stim}$  (2.5ms and 5ms) underestimate the experimental  $\alpha$ . In addition, the line fits also return smaller intercept values then. We see  $t_{max} < 0$  up to  $l/|v| \approx 13.5\text{ms}$  – LGMD activity peaks after ttc! Or, in other words, LGMD activity continues to increase after ttc. In the limit, where stimulus dynamics is extremely fast, and LGMD processes are kept far from equilibrium at each instant of the approach,  $\alpha$  gets very small. As a consequence,  $t_{max}$  gets largely independent of  $l/|v|$ : The activity peak would cling to  $t_{max}$  although we varied  $l/|v|$ .

### 4 Freeze! Experimental data versus steady state of “psi”

In the previous section, experimentally plausible values for  $\alpha$  were obtained if  $\psi$  is close to equilibrium at each instant of time during stimulation. In this section we will thus introduce a steady-state

<sup>6</sup>Assuming one  $\Delta t_{stim}$  for each integration time step. This means that by default stimulation and biophysical dynamics will proceed at identical time scales.

<sup>7</sup>Notice that in this moment we can only make relative statements - we do not have data at hand for defining absolute time scales

Figure 3: Each curve shows how the peak  $\hat{\psi}_\infty \equiv \psi_\infty(\hat{t})$  depends on the half-size-to-velocity ratio. In each display, one parameter of  $\psi_\infty$  is varied (legend), while the others are held constant (figure title). Line slopes vary according to parameter values. Symbol sizes are scaled according to rmse (see also figure 4). Rmse was calculated between normalized  $\psi_\infty(t)$  & normalized  $\eta(t)$  (i.e. both functions  $\in [0, 1]$  with original minimum and maximum indicated by the textbox). To this end, the peak of the  $\eta$ -function was placed at  $t_c$ , by choosing, at each parameter value,  $\alpha = |v| \cdot (t_c - \hat{t})/l$  (for determining correlation, the mean value of  $\alpha$  was taken across  $l/|v|$ ).

Figure 4: This figure complements figure 3. It visualizes the time averaged absolute difference between normalized  $\psi_\infty(t)$  & normalized  $\eta(t)$ . For  $\eta$ , its value of  $\alpha$  was chosen such that the maxima of both functions coincide. Although not being a fit, it gives a rough estimate on how the shape of both curves deviate from each other. The maximum possible difference would be one.

version of  $\psi$  (i.e. equation 2 with  $V_{rest} = 0$ ,  $V_{exc} = 1$ , and equations 3 plugged in),

$$\psi_\infty(t) \equiv \frac{\dot{\Theta}(t) + V_{inh} [\gamma \Theta(t)]^e}{\beta + \dot{\Theta}(t) + [\gamma \Theta(t)]^e} \quad (4)$$

(Here we use continuous versions of angular size and rate of expansion). The  $\psi_\infty$ -function makes life easier when it comes to fitting experimental data. However, it has its limitations, because we brushed the whole dynamic of  $\psi$  under the carpet. Figure 3 illustrates how the linear relationship (“linearity”) between  $t_{max} \equiv t_c - \hat{t}$  and  $l/|v|$  is influenced by changes in parameter values. Changing any of the values of  $e$ ,  $\beta$ ,  $\gamma$  predominantly causes variation in line slopes. The smallest slope changes are obtained by varying  $V_{inh}$  (data not shown; we checked  $V_{inh} = 0, -0.001, -0.01, -0.1$ ). For  $V_{inh} \lesssim -0.01$ , linearity is getting slightly compromised, as slope increases with  $l/|v|$  (e.g.  $V_{inh} = -1 \rightsquigarrow \alpha \in [4.2, 4.7]$ ).

In order to get a notion about how well the shape of  $\psi_\infty(t)$  matches  $\eta(t)$ , we computed time-averaged difference measures between normalized versions of both functions (details: figure 3 & 4). Bigger values of  $\beta$  match  $\eta$  better at smaller, but worse at bigger values of  $l/|v|$  (figure 4a). Smaller  $\beta$  cause less variation across  $l/|v|$ . As to variation of  $e$ , overall curve shapes seem to be best aligned with  $e = 3$  to  $e = 4$  (figure 4b). Furthermore, better matches between  $\psi_\infty(t)$  and  $\eta(t)$  correspond to bigger values of  $\gamma$  (figure 4c). And finally,  $V_{inh}$  marches again to a different tune (data not shown).  $V_{inh} = -0.1$  leads to the best agreement ( $\approx 0.04$  across  $l/|v|$ ) of all  $V_{inh}$ , quite different from the other considered values. For the rest,  $\psi_\infty(t)$  and  $\eta(t)$  align the same (all have maximum 0.094),

Figure 5: The original data (legend label “HaGaLa95”) were resampled from ref. [10] and show DCMD responses to an object approach with  $\dot{\Theta} = const.$  Thus,  $\Theta$  increases linearly with time. The  $\eta$ -function (fitting function:  $A\eta(t+\delta)+o$ ) and  $\psi_\infty$  (fitting function:  $A\psi_\infty(t)+o$ ) were fitted to these data: (a) (Figure 3 Di in [10]) Good fits for  $\psi_\infty$  are obtained with  $e = 5$  or higher ( $e = 3 \rightsquigarrow R^2 = 0.35$  and  $rmse = 0.644$ ;  $e = 4 \rightsquigarrow R^2 = 0.45$  and  $rmse = 0.592$ ). “Psi” adopts a sigmoid-like curve form which (subjectively) appears to fit the original data better than  $\eta$ . (b) (Figure 3 Dii in [10]) “Psi” yields an excellent fit for  $e = 3$ .

Figure 6: (a) DCMD activity in response to a black square ( $l/v = 30ms$ , legend label “e011pos14”, ref. [30]) approaching to the eye center of a gregarious locust (final visual angle  $50^\circ$ ). Data show the first stimulation so habituation is minimal. The spike trace (sampled at  $10^4 Hz$ ) was full wave rectified, lowpass filtered, and sub-sampled to 1ms resolution. Firing rate was estimated with Savitzky-Golay filtering (“sgolay”). The fits of the  $\eta$ -function ( $A\eta(t+\delta)+o$ ; 4 coefficients) and  $\psi_\infty$ -function ( $A\psi_\infty(t)$  with fixed  $e, o, \delta, V_{inh}$ ; 3 coefficients) provide both excellent fits to firing rate. (b) Fitting coefficient  $\alpha$  ( $\rightarrow \eta$ -function) inversely correlates with  $\beta$  ( $\rightarrow \psi_\infty$ ) when fitting firing rates of another 5 trials as just described (continuous line = line fit to the data points). Similar correlation values would be obtained if  $e$  is fixed at values  $e = 2.5, 4, 5 \rightsquigarrow c = -0.95, -0.96, -0.91$ . If  $o$  was determined by the fitting algorithm, then  $c = -0.70$ . No clear correlations with  $\alpha$  were obtained for  $\gamma$ .

despite of covering different orders of magnitude with  $V_{inh} = 0, -0.001, -0.01$ .

**Decelerating approach.** Hatsopoulos *et al.* [10] recorded DCMD activity in response to an approaching object which projected image edges on the retina moving at constant velocity:  $\dot{\Theta} = const.$  implies  $\Theta(t) = \Theta_0 + \dot{\Theta}t$ . This “linear approach” is perceived as if the object is getting increasingly slower. But what appears a relatively unnatural movement pattern serves as a test for the functions  $\eta$  &  $\psi_\infty$ . Figure 5 illustrates that  $\psi_\infty$  passes the test, and consistently predicts that activity sharply rises in the initial approach phase, and subsequently declines ( $\eta$  passed this test already in the year 1995).

**Spike traces.** We re-sampled about 30 curves obtained from LGMD recordings from a variety of publications, and fitted  $\eta$  &  $\psi_\infty$ -functions. We cannot show the results here, but in terms of goodness of fit measures, both functions are in the same ballpark. Rather, figure 6a shows a representative example [30]. When  $\alpha$  and  $\beta$  are plotted against each other for five trials, we see a strong inverse correlation (figure 6b). Although five data points are by no means a firm statistical sample, the strong correlation could indicate that  $\beta$  and  $\alpha$  play similar roles in both functions. Biophysically,  $\beta$  is the leakage conductance, which determines the (passive) membrane time constant  $\tau_m \propto 1/\beta$  of the neuron. Voltage drops within  $\tau_m$  to  $\exp(-1)$  times its initial value. Bigger values of  $\beta$  mean shorter  $\tau_m$  (i.e., “faster neurons”). Getting back to  $\eta$ , this would suggest  $\alpha \propto \tau_m$ , such that higher (absolute) values for  $\alpha$  would possibly indicate a slower dynamic of the underlying processes.

## 5 Discussion (“The Good, the Bad, and the Ugly”)

Up to now, mainly two classes of LGMD models existed: The phenomenological  $\eta$ -function on the one hand, and computational models with neuronal layers presynaptic to the LGMD on the other (e.g. [25, 15]; real-world video sequences & robotics: e.g. [3, 14, 32, 2]). Computational models predict that LGMD response features originate from excitatory and inhibitory interactions in – and between – presynaptic neuronal layers. Put differently, non-linear operations are generated in the presynaptic network, and can be a function of many (model) parameters (e.g. synaptic weights, time constants, etc.). In contrast, the  $\eta$ -function assigns concrete nonlinear operations to the LGMD [7]. The  $\eta$ -function is accessible to mathematical analysis, whereas computational models have to be probed with videos or artificial stimulus sequences. The  $\eta$ -function is vague about biophysical parameters, whereas (good) computational models need to be precise at each (model) parameter value. The  $\eta$ -function establishes a clear link between physical stimulus attributes and LGMD activity: It postulates what is to be computed from the optical variables (OVs). But in computational models, such a clear understanding of LGMD inputs cannot always be expected: Presynaptic processing may strongly transform OVs.

The  $\psi$  function thus represents an intermediate model class: It takes OVs as input, and connects them with biophysical parameters of the LGMD. For the neurophysiologist, the situation could hardly be any better. Psi implements the multiplicative operation of the  $\eta$ -function by shunting inhibition (equation 1:  $V_{exc} \approx V_{rest}$  and  $V_{inh} \approx V_{rest}$ ). The  $\eta$ -function fits  $\psi$  very well according to our dynamical simulations (figure 1), and satisfactory by the approximate criterion of figure 4.

We can conclude that  $\psi$  implements the  $\eta$ -function in a biophysically plausible way. However,  $\psi$  does neither explicitly specify  $\eta$ 's multiplicative operation, nor its exponential function  $\exp(\cdot)$ . Instead we have an interaction between shunting inhibition and a power law  $(\cdot)^e$ , with  $e \approx 3$ . So what about power laws in neurons?

Because of  $e > 1$ , we have an expansive nonlinearity. Expansive power-law nonlinearities are well established in phenomenological models of simple cells of the primate visual cortex [1, 11]. Such models approximate a simple cell's instantaneous firing rate  $r$  from linear filtering of a stimulus (say  $Y$ ) by  $r \propto ([Y]^+)^e$ , where  $[\cdot]^+$  sets all negative values to zero and lets all positive pass. Although experimental evidence favors linear thresholding operations like  $r \propto [Y - Y_{thres}]^+$ , neuronal responses can behave according to power law functions if  $Y$  includes stimulus-independent noise [19]. Given this evidence, the power-law function of the inhibitory input into  $\psi$  could possibly be interpreted as a phenomenological description of presynaptic processes.

The power law would also be the critical feature by means of which the neurophysiologist could distinguish between the  $\eta$  function and  $\psi$ . A study of Gabbiani *et al.* aimed to provide direct evidence for a neuronal implementation of the  $\eta$ -function [8]. Consequently, the study would be an evidence for a biophysical implementation of “direct” multiplication via  $\log \dot{\Theta} - \alpha\Theta$ . Their experimental evidence fell somewhat short in the last part, where “exponentiation through active membrane conductances” should invert logarithmic encoding. Specifically, the authors observed that “In 7 out of 10 neurons, a third-order power law best described the data” (sixth-order in one animal). *Alea iacta est.*
