Abstract

We advance both the theory and practice of robust $\ell_p$-quasinorm regression for $p \in (0, 1]$ by using novel variants of iteratively reweighted least-squares (IRLS) to solve the underlying non-smooth problem. In the convex case, $p = 1$, we prove that this IRLS variant converges globally at a linear rate under a mild, deterministic condition on the feature matrix called the stable range space property. In the non-convex case, $p \in (0, 1)$, we prove that under a similar condition, IRLS converges locally to the global minimizer at a superlinear rate of order $2 - p$; the rate becomes quadratic as $p \to 0$. We showcase the proposed methods in three applications: real phase retrieval, regression without correspondences, and robust face restoration. The results show that (1) IRLS can handle a larger number of outliers than other methods, (2) it is faster than competing methods at the same level of accuracy, (3) it restores a sparsely corrupted face image with satisfactory visual quality.

1 Introduction

Given a feature matrix $A \in \mathbb{R}^{m \times n}$ with $m \gg n$ and a response vector $y \in \mathbb{R}^m$, the problem

$$\min_{x \in \mathbb{R}^n} \|Ax - y\|_p$$

of $\ell_p$-regression has a variety of different applications depending on the choice of $\|v\|_p = (\sum_i |v_i|^p)^{1/p}$. While $p = 2$ corresponds to standard linear regression, the choice of $p > 2$ arises naturally in semi-supervised learning on graphs [1, 2, 3], and a lot of activity has been dedicated recently to the computational complexity analysis for the case $p > 1$ [4, 5, 6].

In this paper, we assume there is a coefficient vector $x^* \in \mathbb{R}^n$ such that the residual $r^* := Ax^* - y$ is $k$-sparse, in which case a choice of $p \in (0, 1]$ is of interest. Indeed, for the convex and non-smooth case $p = 1$, (1) is known as least absolute deviation, which dates back to the time of Boscovich around in the middle of the 18th century [7, 8]. Since then, it has been known intuitively that (1) ($p = 1$) is robust to large but few measurement errors (quoting [9]), i.e., that (1) is robust to outliers. The algorithmic and theoretical understanding of (1) for $p = 1$ has been of long-standing interest to statisticians, which has led to a vast literature spanning from the classic 1964 paper of Huber [10] to recent contributions [11, 12, 13, 14, 15, 16, 17, 18, 19, 20]. That being said, for $p = 1$, there is
Algorithm 1: IRLS for $\ell_p$-Regression ($\text{IRLS}_p$)

1. **Input**: $A = [a_1, \ldots, a_m]^\top \in \mathbb{R}^{m \times n}$, $y = [y_1, \ldots, y_m]^\top \in \mathbb{R}^m$, $p \in (0, 1)$;

2. **Weight initialization**: $w^{(0)} = [w_1^{(0)}, \ldots, w_m^{(0)}] \in \mathbb{R}^m$; // Instead, one can initialize some vector $x^{(1)}$.

3. For $t \leftarrow 0, 1, \ldots$:
   
   \[
   x^{(t+1)} \leftarrow \underset{x \in \mathbb{R}^n}{\arg\min} \sum_{i=1}^m w_i^{(t)} (a_i^\top x - y_i)^2 \quad (2)
   \]

   Update $\epsilon^{(t+1)}$ suitably based on $x^{(t+1)}$, $A$, and $y$; // See Section 2.2 for details.

   \[
   w_i^{(t+1)} \leftarrow \max \{ |a_i^\top x^{(t+1)} - y_i|, \epsilon^{(t+1)} \}^{p-2} \quad \forall i = 1, \ldots, m \quad (3)
   \]

A close, but somewhat underexplored connection between (1) and the basis pursuit problem [21], and more specifically, the techniques [22, 23, 24] and algorithmic aspects [25, 26, 27] of compressed sensing [28] (see also Section 2.1). For $p \in (0, 1)$, problem (1) is non-smooth and non-convex, and generally less well understood. To the best of our knowledge, the only paper that considered (1) with $p \in (0, 1)$ is [29], where the authors presented a condition (based on restricted isometry constants) that guarantees exact recovery of $x^*$ from (1). Other related works come either from the compressed sensing literature, where an $\ell_p$ (and noisy) version of basis pursuit has been considered as a sparsity-promoting formulation [30, 31, 32, 26, 33, 34, 35, 36, 37], or from the literature of matrix recovery/completion, where the Schatten-$p$ norm has come into play as a non-convex surrogate for rank minimization [38, 39, 40, 41, 42, 43]. A key message from these works is that $\ell_p$ or Schatten-$p$ minimization with $p \in (0, 1)$ offers better information-theoretic properties (e.g., requires fewer samples for exact recovery) than minimization with $p = 1$.

Here, we study an iteratively reweighted least-squares method ($\text{IRLS}_p$) to solve (1) with $p \in (0, 1]$. As listed in Algorithm 1, $\text{IRLS}_p$ alternates between solving a weighted least-squares problem (2) and updating the weights (3); see Section 2.2 for more elaboration on IRLS. The simplicity of this idea (with its impressive performance) justifies its popularity in many machine learning [44, 45, 46, 47] and computer vision [48, 49, 50, 51, 52] applications. Based on recent advances on IRLS [26, 27], we make several contributions for understanding (1) and $\text{IRLS}_p$. We state our contributions next.

The Stable Range Space Property (Section 3.1). We put forward the use of the (stable) range space property (RSP) for studying the robust regression problem (1). The stable RSP was proposed by [53] in a different context to analyze a compressed sensing algorithm for solving a weighted basis pursuit problem at each iteration. In analogy to the nullspace property in compressed sensing [24, 28], we show that the RSP is a necessary and sufficient condition for guaranteeing that the $\ell_p$-regression problem in (1) admits $x^*$ as its unique solution (Proposition 2). Moreover, we show that if $A \in \mathbb{R}^{m \times n}$ has i.i.d. $\mathcal{N}(0, 1)$ entries and if $m$ is large enough, then the (stable) RSP holds with high probability (Proposition 3). This justifies its use as the core assumption in our analysis.

Global Linear Convergence (Section 3.2). We prove in Theorem 1 that, under a stable RSP assumption and with $\epsilon^{(t)}$ suitably updated, the $\text{IRLS}_p$ Algorithm 1 with $p = 1$ converges linearly to the ground-truth $x^*$ from any initial weight $w^{(0)}$ (or equivalently from any initial point $x^{(1)}$). Note that while (accelerated) first-order methods (e.g., (sub-)gradient descent and proximal algorithms) can also solve the convex and non-smooth problem (1) with $p = 1$, they exhibit, in general, (global) sub-linear rates at best [54, 55]. To our knowledge, [17] is the only paper that claims global linear convergence of a different IRLS variant for (1) with $p = 1$; we compare our results with the ones of [17] in Section 3.2. On the other hand, Theorem 1 is inspired by the IRLS method of [27] for basis pursuit; based on [27], we suitably modify their proof strategy, and thus obtain a faster linear rate.

Local Superlinear Convergence (Section 3.3). We prove in Theorem 2 that, under a stable RSP assumption and with $\epsilon^{(t)}$ suitably updated, the $\text{IRLS}_p$ Algorithm 1 with $p \in (0, 1)$ converges to $x^*$ superlinearly, provided that $x^{(1)}$ falls into a certain neighborhood of $x^*$. To the best of our knowledge, no similar result exists for $\ell_p$-regression (1). While Theorem 2 is inspired by the IRLS algorithm of [26] for $\ell_p$-basis pursuit, their IRLS method does not work well for small $p$ (Section 2.2), and unlike in our work, their radius of local convergence diminishes greatly as $p \to 0$ or $m \to \infty$.
Applications (Section 4). We illustrate the performance of IRLS, for real phase retrieval [56, 57], linear regression without correspondences [58, 59, 60, 61], and face restoration from sparsely corrupted measurements [62, 63, 64]. For real phase retrieval (Section 4.1), we show that IRLS solves [26, 81] needs only \( m = 2n - 1 \) measurements to recover \( x^* \) up to sign, with an additional assumption. Theoretically, even brute-force can fail to identify vectors with too many non-zero coordinates. For \( p \) fixed, IRLS [26, 17, 80, 27, 81] is also called basis pursuit [75]. Problems (1) and (4) are known to be related in the following sense (as implicitly stated in [21, 29]):

\[
\min_{r \in \mathbb{R}^n} \|r\|_p \quad \text{s.t.} \quad Dr = z
\]

where \( D \) is a \((m - n) \times m\) matrix, \( z \in \mathbb{R}^{m-n} \) a vector and the objective \( \|r\|_p \) penalizes coefficient vectors with too many non-zero coordinates. For \( p = 1 \), (4) is also called basis pursuit [75]. Problems (1) and (4) are known to be related in the following sense (as implicitly stated in [21, 29]):

**Proposition 1.** Suppose that the range space of \( A \) is equal to the nullspace of \( D \), and that \( z = -Dy \). If \( x_1 \) globally minimizes (1), then \( r_1 := Ax_1 - y \) globally minimizes (4). On the other hand, if \( r_2 \) globally minimizes (4), then there exists some \( x_2 \) with \( r_2 = Ax_2 - y \) that globally minimizes (1).

Proposition 1 sheds light on how we “transfer”, with new insights, from the analysis of [26, 27] for (4) to results for (1). In what follows, we treat [26, 27] in the context of robust regression and highlight the contribution of our work relative to [26, 27] and other existing results, whenever possible.

2 Background

2.1 Connection of Robust Regression and Compressed Sensing

The \( \ell_p \)-regression problem (1) has a natural correspondence to the sparse recovery problem

\[
\min_{r \in \mathbb{R}^n} \|r\|_p \quad \text{s.t.} \quad Dr = z
\]

where \( D \) is a \((m - n) \times m\) matrix, \( z \in \mathbb{R}^{m-n} \) a vector and the objective \( \|r\|_p \) penalizes coefficient vectors with too many non-zero coordinates. For \( p = 1 \), (4) is also called basis pursuit [75]. Problems (1) and (4) are known to be related in the following sense (as implicitly stated in [21, 29]):

**Proposition 1.** Suppose that the range space of \( A \) is equal to the nullspace of \( D \), and that \( z = -Dy \). If \( x_1 \) globally minimizes (1), then \( r_1 := Ax_1 - y \) globally minimizes (4). On the other hand, if \( r_2 \) globally minimizes (4), then there exists some \( x_2 \) with \( r_2 = Ax_2 - y \) that globally minimizes (1).

Proposition 1 sheds light on how we “transfer”, with new insights, from the analysis of [26, 27] for (4) to results for (1). In what follows, we treat [26, 27] in the context of robust regression and highlight the contribution of our work relative to [26, 27] and other existing results, whenever possible.

2.2 Iteratively Reweighted Least-Squares: The Basics and New Insights

We first discuss two different updating rules for the smoothing parameter \( \epsilon(t) \) of Algorithm 1: the fixed rule and the dynamic rule. We then consider the weight updating strategy (3). Along the way we use synthetic experiments to illustrate ideas; see Appendix D for the experimental setup. In doing so, we intend to provide a review of the state-of-the-art on the variants of IRLS.

**Fixed Smoothing Parameter.** Instead of updating \( \epsilon(t) \) at each iteration, most works on IRLS use a fixed and small positive number, e.g., \( \epsilon := \epsilon(t) = 0.001 \) for each \( t \) [44, 76, 45, 47, 49, 51, 50, 77]. The intuition is to avoid division by the potentially very small residual \( |a_i^\top x(t) - y_i| \). But this common practice of fixing \( \epsilon \) comes with at least three issues. First, IRLS with a fixed \( \epsilon > 0 \) converges only to an “\( \epsilon \)-approximate” point, not exactly the global minimizer ([78, 79, 44, 76], Figure 1a). Second, even if setting \( \epsilon \) small (e.g., \( \epsilon = 10^{-15} \)) could lead to an accurate enough solution for \( p = 1 \) (Figure 1a), it can fail for \( p < 1 \) (Figure 1b). Finally, it makes obtaining a global linear convergence rate guarantee difficult: We are not aware of any theory about a global linear rate of IRLS with fixed \( \epsilon \).

**Dynamic Smoothing Parameter.** Researchers have used different insights to reach the consensus of dynamically updating \( \epsilon(t) \) [26, 17, 80, 27, 81]. The first insight is that convergence to global minimizers ensues if \( \epsilon(t) \) is suitably decreased to 0 [26]. With \( \beta \in (0, 1) \), one such decreasing rule is

\[
\epsilon(t+1) \leftarrow \beta \epsilon(t) \quad \text{if certain conditions are satisfied, or keep } \epsilon(t+1) \leftarrow \epsilon(t) \text{ otherwise} \quad [17, 81].
\]

Figure 1a depicts the performance of [17] with an arbitrary choice \( \beta = 0.5 \) and \( \epsilon(0) = 1 \). Also shown in Figure 1a are the IRLS methods with update rules of [26] and [27], which we discuss next.

The basis pursuit paper [26] also proposed a dynamic updating rule for \( \epsilon(t) \). In our context (1), it sets

\[
\epsilon(0) \leftarrow \infty, \quad \epsilon(t+1) \leftarrow \min \{ \epsilon(t), \|r(t+1)\|_0/m \}, \quad r(t+1) := Ax(t+1) - y \in \mathbb{R}^m.
\]
we note that overestimating the sparsity level

where the hyper-parameter \( \alpha \) is a non-negative integer, and \([r^{(t+1)}]_{\alpha+1}\) is the \((\alpha + 1)\)-th largest element of the residual \(r^{(t+1)}\) in absolute values. Clearly, (6) creates a non-increasing sequence of smoothing parameters \(\epsilon^{(t)}\), and the decay rate of \(\epsilon^{(t)}\) is adaptive to the data (in this case to the residual \(r^{(t+1)}\)). While at first glance it is not clear how fast \(\epsilon^{(t)}\) decays, [26] showed that the decay rate of \(\epsilon^{(t)}\) in (6) is locally linear for \(p = 1, \alpha = k\) under mild conditions, in accordance with the decay of the objective values.

The final dynamic update rule for the parameter \(\epsilon^{(t)}\) is from [27] and improves upon (6) [26] via:

\[
\begin{align*}
\epsilon^{(0)} & \leftarrow \infty, \\
\epsilon^{(t+1)} & \leftarrow \min \left\{ \epsilon^{(t)}, \sigma^{(t+1)}/m \right\} \\
\text{where } \sigma^{(t+1)} & \leftarrow \min \left\{ \|r^{(t+1)} - z\|_1 : z \in \mathbb{R}^m \text{ is } \alpha\text{-sparse} \right\}
\end{align*}
\]

Observe that (7) computes the \(\ell_1\)-norm \(\sigma^{(t+1)}\) of the best \(\alpha\)-term approximation of the residual \(r^{(t+1)}\), which is in general larger than \([r^{(t+1)}]_{\alpha+1}\) of (6), while both update rules (6) and (7) rely on the hyper-parameter \(\alpha\). Ideally, if \(\alpha = k\), and if IRLS with (6) or (7) converges to \(x^*\), then both \([r^{(t+1)}]_{\alpha+1}\) and \(\sigma^{(t+1)}\) will approach 0 for large enough \(t\). While update rules (6) and (7) perform similarly for \(\ell_1\)-regression (Figure 1a), (6) fails more easily for small \(p\) than (7) (Figure 1b). Finally, we note that overestimating the sparsity level \(k\) by setting \(\alpha > k\) deteriorates the performance of (7) only slightly (Figure 1c).

**Summary.** In Section 2.2 we delivered two take-away messages: (1) IRLS with a fixed \(\epsilon^{(t)}\) finds some approximate solution, sometimes good enough, (2) dynamically updating \(\epsilon^{(t)}\) as per (5)-(7) leads to local [26] or global [17, 27] linear convergence guarantees. In view of Figure 1, we will next consider the IRLS\(_p\) Algorithm 1 with update rule (7) for \(\epsilon^{(t)}\), and analyze its convergence rates.

### 3 Convergence Theory of IRLS for Robust Regression

In Section 3.1 we introduce the stable range space property and justify it as our core assumption. Under this assumption, we prove the global linear convergence (Theorem 1) and local superlinear convergence (Theorem 2) of the IRLS\(_p\) Algorithm 1 in Sections 3.2 and 3.3, respectively.

#### 3.1 The Stable Range Space Property

**Definition 1** (Stable Range Space Property). A matrix \(A \in \mathbb{R}^{m \times n}\) is said to satisfy the range space property (RSP) of order \(k\), or the \(k\)-RSP for short, if the following holds for any vector \(d\) in the range

\[\text{In [26] and [27], } \alpha \text{ is the sparsity level } k, \text{ but } k \text{ might be unknown in practice, so we treat it as a hyper-parameter. That being said, in the experiments we set } \alpha = k \text{ by default, for simplicity and in light of Figure 1c.}\]
space of $A$ and any set $S \subset \{1, \ldots, m\}$ of cardinality at most $k$:

$$
\sum_{i \in S} |d_i| < \sum_{i \in S^c} |d_i|
$$

(8)

The stable RSP of $A$ is defined in the same way as the RSP except that we now require

$$
\sum_{i \in S} |d_i| \leq \eta \sum_{i \in S^c} |d_i|
$$

(9)

for some $\eta \in (0, 1)$. We write "$(k, \eta)$-stable RSP" to emphasize the parameters $k$ and $\eta$.

By definition, the stable RSP implies the RSP. Note that the $(k, \eta)$-stable RSP was proposed in [53] to analyze a reweighted $\ell_1$-minimization algorithm for compressed sensing. With the notation of Proposition 1, we can see that checking (8) for all $d$ in the range space of $A$ is equivalent to checking it for all $d$ in the nullspace of $D$, the latter being the well-known nullspace property (NSP) [24, 28]. In other words, the (stable) RSP of $A$ is equivalent to the (stable) NSP of $D$.

In Sections 3.2 and 3.3, we will use the $(k, \eta)$-stable RSP as an assumption for analysis. Arguably, this is a weak assumption to make as the (stable) RSP is very close to a sufficient and necessary condition for exact recovery of the coefficient vector via $\ell_p$-robust regression (1):

**Proposition 2** (Exact Recovery $\Leftrightarrow$ RSP). Let $p \in (0, 1]$. For all $x^*$ and $y$ such that $Ax^* - y$ is $k$-sparse $x^*$ is the unique solution to (1) if and only if $A \in \mathbb{R}^{m \times n}$ satisfies the $k$-RSP.

It follows from [82, Theorem 5] and Proposition 1 that checking whether a given matrix $A$ satisfies the stable RSP is co-NP-complete [83]. On the other hand, we show that random Gaussian matrices of size $m \times n$ with sufficiently large $m$ satisfy the stable RSP with high probability, which further justifies the usage of the stable RSP as an assumption in our analysis of IRLS$_p$:

**Proposition 3** (Gaussian $\Rightarrow$ RSP). Suppose $m - n \geq 2k$. Let $A \in \mathbb{R}^{m \times n}$ be a matrix with i.i.d. $\mathcal{N}(0, 1)$ entries. Let $\delta \in (0, 1)$ and $\eta \in (0, 1]$ be fixed constants. If it holds that

$$
\frac{(m - n)^2}{m - n + 1} \geq 2k \ln(em/k) \cdot \left(1.67 + \eta^{-1} + \frac{\sqrt{18 \ln(2.5\delta^{-1})}}{\sqrt{2k \ln(em/k)}}\right)^2,
$$

(10)

then $A$ satisfies the $(k, \eta)$-stable RSP with probability at least $1 - \delta$.

The assumption $m - n \geq 2k$ of Proposition 3 is necessary, as it is not hard to prove that, if $m - n < 2k$ and $Ax^* - y$ is $k$-sparse, then the $\ell_0$-minimization problem $\min_{x \in \mathbb{R}^n} \|Ax - y\|_0$ has multiple solutions. With this assumption, (10) roughly becomes $m - n \geq ck \log(em/k)$ for some constant $c$ if $m - n$ is large enough; thus, ignoring logarithmic and constant factors, condition (10) becomes $m - n \geq \Theta(k)$, which is nearly optimal, as the condition $m - n \geq 2k$ is necessary.

Proposition 2 follows directly from [28, Theorem 4.9], so we omit its proof. The reader might also find Proposition 3 corresponds to [28, Corollary 9.34]. This corollary assumes $D$ of (4) has i.i.d. $\mathcal{N}(0, 1)$ entries, from which is not immediate what the distribution of $A$ is, thus it does not imply Proposition 3 directly; this is why we provide a complete proof for Proposition 3 in Appendix C.1.

### 3.2 Global Linear Convergence of IRLS$_1$.

With the background provided in Section 2, we are now ready to state the first main result:

**Theorem 1** (Global Linear Convergence). Suppose $A \in \mathbb{R}^{m \times n}$ obeys the $(k, \eta)$-stable RSP with $\eta \in (0, 3/4]$ (cf. Definition 1). Let $Ax^* - y$ be $k$-sparse. If the smoothing parameter $\varepsilon(t)$ is updated as per (7) with $\alpha = k$ during the execution of the IRLS$_1$ Algorithm 1, then it holds for any $t \geq 1$ that

$$
\|Ax^{(t+1)} - y\|_1 - \|Ax^* - y\|_1 \leq \left(1 - \frac{(3-4\eta)^2}{294\eta m}\right)^t \cdot 3 \cdot \|Ax^{(1)} - y\|_1,
$$

(11)

meaning that the IRLS$_1$ Algorithm 1 converges linearly and globally in objective value.

**Discussion.** The condition $\eta \in (0, 3/4)$ is better understood via Proposition 3, which asserts that this condition holds with high probability if $A$ has i.i.d. Gaussian entries and if $m$ is large enough
was pointed out for IRLS for basis pursuit in [27]. That being said, we conjecture that the linear

**Theorem 2**

Run IRLS\(_p\) with \(p \in [0, 1]\) and update \(\epsilon(t)\) by (7) with \(\alpha = k\). Assume \(A\) satisfies the \((k, \eta)\)-stable RSP (Definition 1). Let \(c \in (0, 1)\) be a sufficiently small constant such that \(2c^{2(1-p)\eta(\eta + 1)} < (1 - c)^{2-p}\). Let \(A\) be \(k\)-sparse with support \(S^*\). Define

\[
\mu := 2\eta(\eta + 1)(1 - c)^{p-2} \cdot \min_{i \in S^*} |a_i^T x^* - y_i|^{p-1}.
\]

If the initialization \(x^{(1)}\) is in a neighborhood of \(x^*\), in the sense that

\[
\|Ax^{(1)} - Ax^*\|_1 \leq c \cdot \min_{i \in S^*} |a_i^T x^* - y_i|,
\]

\(\text{compared to } n, k\). Moreover, if the \((k, \eta)\)-stable RSP holds, Proposition 2 implies that \(x^*\) is a global minimizer of (1) with \(p = 1\). The strength of Theorem 1 is in that it guarantees linear convergence for any initialization, starting at the first iteration. However, the price to pay is that the convergence rate seems conservative with constant \(1/294\), and depends on the number \(m\) of samples: (11) predicts that IRLS\(_1\) converges with accuracy \(\delta\) in \(O(m \log(1/\delta))\) iterations and \(m\) can be large. We argue that such dependency is not an artifact of our analysis, because similar dependencies have been established for IRLS variants for \(\ell_p\)-regression (1) with \(p > 2\) [27, Theorem 3.1], for interior point methods in convex optimization with \(m\) inequality constraints ([84, Chapter 11], [55, Chapter 5]), and for SGD in smooth & strongly convex optimization with a sum of \(m\) function components [85, Theorem 2.1]). Moreover, an adversarial initialization for which the rate empirically depends on \(m\) was pointed out for IRLS for basis pursuit in [27]. That being said, we conjecture that the linear dependency on \(m\) in (11) can be improved to \(\sqrt{m} \log m\) for some different choice of \(\epsilon(t)\); see [27] and [84, Sections 11.5 and 11.8.2] for why this conjecture makes sense. Furthermore, Figure 1a empirically depicts that, with the least-squares initialization, i.e., with \(w_i^{(0)} = 1\) for all \(i\), IRLS\(_1\) typically converges to \(x^*\) in 30 iterations. This hints to the possibility of alleviating the dependency on \(m\) by analyzing the least-squares initialization, a challenging task which we leave to future work.

**Comparison to [17].** To our knowledge, [17] is the only paper that claimed the global linear convergence of an IRLS variant with \(\epsilon(t)\) updated as per (5) and with \(p = 1\). In particular, [17] sets \(\epsilon(t+1) \leftarrow \beta \epsilon(t)\) whenever \(\|x^{(t+1)} - x^*(t)\|_2 \leq 2\beta \epsilon(t)\); see Figure 1a for the convergence of IRLS under this rule. The update rule \(\epsilon(t+1) \leftarrow \beta \epsilon(t)\) of [17] has the advantage of being faster to compute than (7). In spite of this, and of their beautiful proof idea, their result has several disadvantages compared to Theorem 1. First, their proof involves sophisticated probabilistic arguments, and is tailored towards a feature matrix that satisfies strong concentration properties. Our analysis, on the other hand, uses the \((k, \eta)\)-stable RSP, which is close to a necessary and sufficient condition for the success of \(\ell_1\)-regression (cf. Proposition 2) and expected to hold for a much larger range of matrices than just (sub-)Gaussian matrices (see [86, 87] for related results in the context of basis pursuit). Second, some statements in their proof are inaccurate (e.g., their Lemma 5 does not hold for \(k < n\), the last paragraph in their proving Lemma 8 is not rigorous). Third, their update rule incurs two hyper-parameters, \(\epsilon(0)\) and \(\beta\), while Theorem 1 is based on the decreasing rule (7) that is adaptive to data, and the only hyper-parameter \(\alpha\) is easier to set (Figure 1c).

**Connection to [27].** A related global linear convergence was established for the IRLS method for basis pursuit in [27, Theorem 3.2]. Our proof is inspired by [27], but also improves on its strategy. For example, their Theorem 3.2 involves two parameters for the \(\text{stable nullspace property}\), while we only have a single RSP parameter \(\eta\), simplifying matters. Also, we obtain a constant of \(1/294\) in Theorem 1, which is better than the value of \(1/768\) for the respective constant in [27, Theorem 3.2].

It is important to note that the proofs of [17, 27] and ours heavily rely on certain rules for decreasing the smoothing parameter \(\epsilon(t)\); all these proofs of global linear convergence for IRLS would break down if \(\epsilon(t)\) were fixed. While the main theorems of both [17] and [27] are limited to the \(p = 1\) case, we present our Theorem 2 for \(p \in (0, 1)\) next.

### 3.3 Local Superlinear Convergence of IRLS\(_p\)

The \(\ell_p\)-regression problem (1) with \(p \in (0, 1)\) is more challenging than the case \(p = 1\) due to the lack of convexity. However, here we show that at least locally, IRLS\(_p\) converges with a superlinear rate of order \(2 - p\). Moreover, since it is valid to run IRLS\(_p\) even with \(p = 0\), we carefully design the proof such that the following result holds not only for \(p \in (0, 1]\), but also for \(p = 0\), in which case IRLS\(_p\) can be interpreted as an algorithm minimizing a sum-of-logarithm objective (see Appendix A.2).

**Theorem 2** (Local Superlinear Convergence). Run IRLS\(_p\) with \(p \in [0, 1]\) and update \(\epsilon(t)\) by (7) with \(\alpha = k\). Assume \(A\) satisfies the \((k, \eta)\)-stable RSP (Definition 1). Let \(c \in (0, 1)\) be a sufficiently small constant such that \(2c^{2(1-p)\eta(\eta + 1)} < (1 - c)^{2-p}\). Let \(A\) be \(k\)-sparse with support \(S^*\). Define

\[
\mu := 2\eta(\eta + 1)(1 - c)^{p-2} \cdot \min_{i \in S^*} |a_i^T x^* - y_i|^{p-1}.
\]

If the initialization \(x^{(1)}\) is in a neighborhood of \(x^*\), in the sense that

\[
\|Ax^{(1)} - Ax^*\|_1 \leq c \cdot \min_{i \in S^*} |a_i^T x^* - y_i|,
\]
then $\text{IRLS}_p$ achieves the following superlinear convergence rate of order $2 - p$ for every $t \geq 1$:

$$
\|A^*(t+1) - Ax^*\|_1 \leq \mu \cdot \left( \|A^*(t) - Ax^*\|_1 \right)^{2-p} \lesssim \mu \cdot \left( \|A^*(t) - Ax^*\|_1 \right)^{2-p}
$$

In particular, for $p \in (0, 1)$, the superlinear rate (14) implies

$$
\|A^*(t+1) - Ax^*\|_1 \lesssim \left( \mu^{1/(1-p)} \cdot \|A^*(1) - Ax^*\|_1 \right)^{(2-p)(t-1)} \cdot \|A^*(1) - Ax^*\|_1.
$$

**Example 1 (Quadratic versus linear rates).** We illustrate the practical benefit of a superlinear (quadratic) convergence rate with the following simple calculation. Suppose that the inequality in (13) is barely fulfilled such that in the case of $p = 0$, $x^{(1)}$ satisfies $\|A^*(1) - Ax^*\|_1 \leq 0.9999999$. Then (15) implies that after 30 iterations, the residual error is far below numerical precision already since $\|A^*(31) - Ax^*\|_1 \leq 0.9999999^{29} \cdot \|A^*(1) - Ax^*\|_1 \approx 10^{-47} \cdot \|A^*(1) - Ax^*\|_1$. On the other hand, for $p = 1$, a linear convergence factor $\mu$ of $\mu \leq 0.9999999$ is only able to guarantee a decay of the order $\cdot \mu^{30} \approx 0.9999999^{30} \approx 0.999997$ after 30 iterations.

**Discussion.** Even though $\text{IRLS}_p$ with $p \in (0, 1)$ is tailored to $\ell_p$-regression, we measure the progress of $\text{IRLS}_p$ in $\ell_1$-norm, e.g., we provide upper bounds on $\|A^*(t+1) - Ax^*\|_1$; this is because doing so avoids the use of Hölder’s inequality, which allows us to give tighter results that improve on [26] (see the next paragraph). The second point that deserves discussion is the local convergence neighborhood defined by the right-hand side of (13). Note that, we typically assume that every outlier sample $(a_i, y_i)$ (with $i \in S^d$) would result in a relatively large residual at $x^*$, say $|a_i|^2 \cdot y_i - y_i^2 > 0$. Hence the minimization term of the right-hand side in (13) is well-behaved. Next, one might ask how to obtain such an initialization $x^{(1)}$ that satisfies (13). One might run $\text{IRLS}_1$ to produce such an initialization; note though that the upper bound of (13) cannot be computed, so one could not detect when to switch from $\text{IRLS}_1$ to $\text{IRLS}_p$, $p \in (0, 1)$. Or alternatively, one could run $\text{IRLS}_p$ with a least-squares initialization and count on empirical global (super)linear convergence of $\text{IRLS}_p$; the latter is what we did in the experiments and is what we recommend. A final and important remark is that $\ell_p$-regression (1) with $p \in (0, 1)$ is in general NP-hard [28, Exercise 2.10], but this does not contradict the theoretical local superlinear convergence of Theorem 2 and the empirical global convergence in Figures 1b and 2b, and this does not mean that $\text{IRLS}_p$ solves an NP-hard problem in polynomial time. The catch is that we operate under the assumption that $x^*$ leads to a $k$-sparse residual and is a unique global minimizer of (1) (cf. Proposition 2). With this assumption and small enough $k/m$, $\ell_p$-regression is tractable and can be solved via $\text{IRLS}_p$ to high accuracy (Figure 1b).

**Connection to [26].** [26, Theorem 7.9] proves the local superlinear convergence of $\text{IRLS}_p$ with update rule (6) for $\ell_p$-basis pursuit (4), which motivates Theorem 2. However, [26, Theorem 7.9] requires $c$ of (13) to satisfy $c = O(1/m^{2/p-1})$, which means that, as $p \to 0$ or $m \to \infty$, the eligible value of $c$ quickly becomes vanishingly small, and thus the radius of local convergence (13) diminishes greatly. In contrast, in our condition $2e^{1-p}(\eta + 1) < (1 - c)^{2-p}$, $c$ has no direct dependency on $m$ and is well-behaved even if $p \to 0$. The above difference is due partly to our improved proof strategy, and partly to the different update rules of the smoothing parameter $\epsilon(t)$. Figure 1b showed that rule (6) of [26] does not work well for small $p$, in contrast to rule (7) that we use; a possible explanation for this phenomenon is that rule (6) decreases $\epsilon(t)$ too fast, yielding a poor initialization for the next iteration of weighted least-squares (similarly to the interior point method, cf. [84]). Finally, [26, Theorem 7.9] does not hold for $p = 0$, for which Theorem 2 still holds and suggests a local quadratic rate.

4 Applications and Experiments

We now explore the performance of $\text{IRLS}_p$ in three different applications, real phase retrieval (Section 4.1), linear regression without correspondences (Section 4.2), and face restoration (Section 4.3). Note that the first two applications are special examples of the recent algebraic-geometric framework called homomorphic sensing [88], [89, Section 4], [90, Section 1.2]. In Section 4.4, we examine the behavior of $\text{IRLS}_p$ for different values of $p$ and under noise.

4.1 Real Phase Retrieval

In real phase retrieval [56, 57], we are given a measurement matrix $A = [\alpha_1, \ldots, \alpha_m]^\top$ and $y = [y_1, \ldots, y_m]^\top$, where $y_i := |\alpha_i^\top x^*|$, and we need to find either $x^*$ or $-x^*$. This problem
is a relative of the complex phase retrieval problem [65], where all data $y$ and $A$, as well as the ground-truth $x^*$, are complex-valued, and which has applications in X-ray crystallography [91].

Here we show that real phase retrieval can be solved via $\ell_p$-regression (1). Consider the index sets

$$I^+ := \{i : a_i^\top x^* > 0\}, \quad I^- := \{i : a_i^\top x^* < 0\}. \quad (16)$$

We might assume $a_i^\top x^* \neq 0$ for every $i$ without loss of generality. Then we know that either $Ax^* - y$ has its $\ell_0$ norm equal to $m - |I^+|$, or $A(-x^*) - y$ has its $\ell_0$ norm equal to $m - |I^-|$. With such sparsity patterns on these two residuals, we can minimize (1), which serves as a (non-convex) relaxation of $\ell_0$-minimization, to recover $x^+$ or $-x^*$, whichever corresponds to a sparser residual. Here, we essentially treat one of the two clusters defined by (16) as inliers, and the other as outliers. This robust regression point of view on real phase retrieval seems to be known by experts [92, Section 1.2], but we have not found a paper that actually proposes to solve (1) for real phase retrieval.

Here we argue with Figure 2a that, solving (1) (by IRLS$_{0.1}$) for real phase retrieval can be beneficial. Indeed, theoretically, IRLS$_{0.1}$ converges to $\pm x^*$ locally but superlinearly (as a corollary of Theorem 2). Empirically, Figure 2a shows that IRLS$_{0.1}$ succeeds in recovering $\pm x^*$ by using only $m = 2n - 1$ samples, which is exactly the theoretical minimum for real phase retrieval [65, Proposition 2.5]. Figure 2a also shows that multiple other state-of-the-art methods$^3$ [57, 67, 68, 69, 70] fail to recover $\pm x^*$ in this extreme situation, even though some of them have nearly optimal sample complexity, which requires roughly $O(n)$ samples up to a logarithmic factor to succeed (caution: nearly optimal $\neq$ optimal). As suggested by Proposition 3, for $|I^+|$ fixed, minimizing (1) with a Gaussian matrix $A$ enjoys $m = O(n)$ sample complexity, up to also a logarithmic factor.

Despite these advantages, we also emphasize that solving (1) (via IRLS$_{0.1}$) for real phase retrieval has an inherent limit: The performance depends on the number $|I^+|$ of positive signs and the number $m$ of samples; we might call $|I^+|/m$ the inlier rate or outlier rate. At $n/m = 200/399$, we see that IRLS$_{0.1}$ succeeds if $|I^+| \leq 70$, and if $|I^+| \geq 399 - 70$ by symmetry, but it fails if $|I^+|$ and $|I^-|$ get closer (Figure 2a). For IRLS$_{0.1}$ to successfully handle the case $|I^+| = |I^-|$, we need more samples, empirically, say $m \geq 5n$. It is an interesting future direction to design an algorithm that can handle the case of minimum samples ($m = 2n - 1$) and balanced data ($|I^+| = |I^-|$).

**4.2 Linear Regression without Correspondences**

Compared to (real) phase retrieval, the problem of linear regression without correspondences is an also important, but less developed subject; see [58, 94, 59, 60, 61, 95, 96, 97] for recent advances. In this problem we are given $y \in \mathbb{R}^m$ and $A \in \mathbb{R}^{m \times n}$, and we need to solve the equations

$$y = \Pi A x \quad (17)$$

for some unknown permutation matrix $\Pi \in \mathbb{R}^{m \times m}$ and vector $x \in \mathbb{R}^n$, under the assumption that there exists a solution $(\Pi^*, x^*)$. Solving (17) is in general NP-hard for $n > 1$ [94, 98]. However, if

$^3$Reviewing these algorithms is beyond the scope of this paper. Some of them are designed for complex phase retrieval but is applicable to the real case. We used the implementations from PhasePack [93].
We show that IRLS we further assume that Theorem 1 and Theorem 2. (IRLS observe that IRLS iterates of
In the first experiment, visualized in Figure 4a, we compare the decay of the relative errors of the
4.4 The Choice of F noise). Figure 3b shows some images randomly chosen from the dataset; observe that Least-Squares
golden baseline, and (3) IRLS = ˜ to estimate x ˜ f i as our measurement; so Fi = Fi, and p = 2, (2) Least-Squares* that solves (1) with A = Fi, y = f i, and p = 2, used as a golden baseline, and (3) IRLS0.1 which solves (1) with A = Fi and y = f i. Figure 3a shows that IRLS0.1 is more robust to salt & pepper noise, whose amount is k/m, than Least-Squares, and has lower error \|f_i - f\|_2/\|f_i\|_2 (recall though that Least-Squares is statistically optimal for Gaussian noise). Figure 3b shows some images randomly chosen from the dataset; observe that Least-Squares tends to “average” the illumination in all images Fi, while IRLS0.1 delivers faithful restoration.

4.4 The Choice of p and Performance of IRLS_p Under Noise

Here we outline two experiments that illustrate two different aspects of IRLS_p empirically.

In the first experiment, visualized in Figure 4a, we compare the decay of the relative errors of the
iterates of IRLS_p for different choices of p in the case that the residual is exactly k-sparse. We observe that IRLS1 exhibits a linear error decay on the one hand and a superlinear decay for IRLS_p with p = 0.5 and p = 0.1 that accelerates as p decreases towards 0, confirming the rates predicted by Theorem 1 and Theorem 2. (p = 1, 0.5, 0.1 are rather arbitrary choices in our experiments.)
In another experiment, visualized in Figure 4b, we explore the robustness of \( \text{IRLS}_p \) if the model assumption of \( k \)-sparse residuals is not satisfied, but only approximately. In particular, the input vector \( y \in \mathbb{R}^m \) of \( \text{IRLS}_p \) is now such that its restriction on \( S^\star \) with \( |S^\star| = k \) has i.i.d. \( \mathcal{N}(0, 1) \) entries (corresponding to the sparse corruptions), but its other coordinates are distributed as independent Gaussian variables with mean \( a_i^\top x^\star \) and variance 0.01, where \( i \in (S^\star)^c \) (corresponding to dense noise); see also the code provided in Appendix D.2. We observe that also for this case of only approximately \( k \)-sparse residuals, \( \text{IRLS}_p \) performs well, with faster and more accurate convergence for \( p = 0.1 \) and \( p = 0.5 \) compared to \( p = 1 \). We note that, strictly speaking, Theorem 1 and Theorem 2 do not apply directly to this case of approximately \( k \)-sparse residuals, but it is not hard to generalize it to this case; see [27, Theorem A.1] for a similar result for IRLS applied to basis pursuit.

5 Discussion and Future Work

In this work, we established novel global linear and local superlinear rates of \( \text{IRLS}_p \) for \( \ell_p \)-regression (1) under the assumption of the stable range space property. Furthermore, we explored several applications for which \( \text{IRLS}_p \) exhibits state-of-the-art results.

There are several directions that deserve further investigation. Theoretically, the Gaussian assumption of Proposition 3 might be weakened; similar results would hold for sub-Gaussian distributions [86, 87]. Note also that, in experiments (Figures 1 and 2), \( \text{IRLS}_p \) works well even when \( m - n \to 2k \). This leaves the question of whether the constant or logarithmic factors of condition (10) are too stringent for guaranteeing the stable RSP to hold; can this be improved? Finally, it is tempting to carry out a global rate analysis of \( \text{IRLS}_p \) with \( p \in (0, 1) \) for \( \ell_p \)-regression; can one prove global (linear) rates under the stable RSP or other assumption?

Algorithmically, designing inexact solvers for the inner (weighted) least-squares problem (2) based on Krylov-subspace methods [101, 102] is expected to further accelerate our current IRLS implementation (our current implementation is attached in Appendix E). Also, our empirical experiments suggest that \( \text{IRLS}_p \) (in particular \( p \in (0, 1) \)) is worth being adopted and applied to many other outlier-robust estimation tasks beyond robust regression [45, 48, 49, 50, 51, 52, 103, 104, 105, 106, 107, 108].

Acknowledgments and Disclosure of Funding

[23] D. L. Donoho, “For most large underdetermined systems of linear equations the minimal $\ell_1$-norm solution is also the sparsest solution,” *Communications on Pure and Applied Mathematics*, vol. 59, no. 6, pp. 797–829, 2006.

**Checklist**

1. For all authors...
   (a) Do the main claims made in the abstract and introduction accurately reflect the paper’s contributions and scope? [Yes] Furthermore, we made a lot of efforts in comparing the theoretical results of prior works and position our contribution in the literature.
   (b) Did you describe the limitations of your work? [Yes] See for example at Lines 268-274 on real phase retrieval. We also discussed several directions for improvements or future research at the end of the paper.
   (c) Did you discuss any potential negative societal impacts of your work? [No]
   (d) Have you read the ethics review guidelines and ensured that your paper conforms to them? [Yes]

2. If you are including theoretical results...
   (a) Did you state the full set of assumptions of all theoretical results? [Yes] In particular, we used an entire subsection (Section 3.1) to justify the major assumption, the stable range space property.
   (b) Did you include complete proofs of all theoretical results? [Yes] We omitted the proofs of Proposition 1 and 2 as they follow directly from existing results; see Line 83 and Line 155. All other theoretical results are proved in the appendix.

3. If you ran experiments...
   (a) Did you include the code, data, and instructions needed to reproduce the main experimental results (either in the supplemental material or as a URL)? [Yes] We attached a copy of our code in the supplemental material.
(b) Did you specify all the training details (e.g., data splits, hyperparameters, how they were chosen)? [Yes] In the appendix, we use an entire section to describe our experimental setup. We did not do that in the main paper in interest of space.

(c) Did you report error bars (e.g., with respect to the random seed after running experiments multiple times)? [No] We did not report error bars for two reasons. The main reason is that some of our figures are quite dense, and adding error bars on them makes it harder to read. A slightly subjective reason is that we believe our current figures are informative enough, correctly deliver the message, and are fair for other methods.

(d) Did you include the total amount of compute and the type of resources used (e.g., type of GPUs, internal cluster, or cloud provider)? [N/A]

4. If you are using existing assets (e.g., code, data, models) or curating/releasing new assets...

(a) If your work uses existing assets, did you cite the creators? [Yes]

(b) Did you mention the license of the assets? [No] In the main paper we used the Extended Yale B face dataset, which is free for research purposes.

(c) Did you include any new assets either in the supplemental material or as a URL? [No]

(d) Did you discuss whether and how consent was obtained from people whose data you’re using/curating? [Yes]

(e) Did you discuss whether the data you are using/curating contains personally identifiable information or offensive content? [No]

5. If you used crowdsourcing or conducted research with human subjects...

(a) Did you include the full text of instructions given to participants and screenshots, if applicable? [N/A]

(b) Did you describe any potential participant risks, with links to Institutional Review Board (IRB) approvals, if applicable? [N/A]

(c) Did you include the estimated hourly wage paid to participants and the total amount spent on participant compensation? [N/A]
A IRLS as Smoothing Method Minimizing Quadratic Models

In this section, we clarify the precise relationship between the steps of IRLS\(_p\) as described in Algorithm 1 and the \(\ell_p\)-objective on the residual, cf. (1).

A.1 IRLS\(_p\) as Lp-Regression for 0 < \(p\) ≤ 1

In Section 2.2, we shed light on the different rules for choosing the smoothing parameter \(\epsilon^{(t+1)}\) in Algorithm 1. In fact, this terminology is used as there is an intimate relationship between the least squares step (2) of IRLS\(_p\) and a smoothed \(\ell_p\)-objective \(H_\epsilon(\cdot)\) which is, for given \(\epsilon > 0\), defined as

\[
H_\epsilon(r) = \sum_{i=1}^{m} h_\epsilon(r_i)
\]

where \(h_\epsilon : \mathbb{R} \to \mathbb{R}\) is a symmetric smoothed one-dimensional function such that

\[
h_\epsilon(r) = \begin{cases} 
\frac{1}{p} |r|^p & |r| > \epsilon \\
\frac{1}{2} \frac{r^2}{\epsilon^2} + \left(\frac{1}{p} - \frac{1}{2}\right) \epsilon^p & |r| \leq \epsilon
\end{cases}
\]

which makes \(H_\epsilon\) a function akin to a scaled \(\ell_p\)-quasinorm, but which is quadratic around 0. This definition corresponds to a scaled Huber loss in the case of \(p = 1\) [10], but extends to the non-convex case if \(0 < p < 1\).

By considering the derivative of \(\epsilon \to h_\epsilon(r)\) for fixed \(r\), it is easy to see that \(h_\epsilon(r)\), and therefore also \(H_\epsilon(r)\), is non-decreasing in \(\epsilon\), which implies that

\[
-\frac{1}{p} \|Ax - y\|_p^p = \lim_{\epsilon \to 0^+} H_\epsilon(Ax - y) \leq H_\epsilon(Ax - y)
\]

for any \(\epsilon > 0\). We note that \(H_\epsilon(\cdot)\) is continuously differentiable, so that the function \(\mathbb{R}^m \times \mathbb{R}_{>0} \to \mathbb{R}, (r, \epsilon) \to H_\epsilon(r)\) can be considered as a smoothing function as defined in the non-smooth optimization literature [109, 110].

In this context, one interpretation of IRLS\(_p\) (and of other IRLS methods such as [111, 26, 17, 27], with possibly different smoothing functions) is to consider it as a smoothing method for \(\ell_p\)-regression with quadratic majorizing models. Indeed, defining the function \(Q_\epsilon : \mathbb{R}^m \times \mathbb{R}^m \to \mathbb{R}\),

\[
Q_\epsilon(v, r) = \sum_{i=1}^{m} q_\epsilon(v_i, r_i), \quad \text{where } q_\epsilon(v, r) = h_\epsilon(r) + \frac{1}{2} \max\{|r|^2, \epsilon^2\} - \frac{r^2}{\epsilon^2},
\]

which is quadratic in \(r\), we observe that the least squares step (2) of IRLS\(_p\) satisfies

\[
x^{(t+1)} = \arg\min_{x \in \mathbb{R}^n} Q_\epsilon(Ax - y, x^{(t)})
\]

where \(r^{(t)} = Ax^{(t)} - y\). Since \(Q_\epsilon(\cdot, r)\) locally coincides with the smoothed function \(H_\epsilon(\cdot)\) so that

\[
H_\epsilon(r) = Q_\epsilon(r, r)
\]

for each \(r \in \mathbb{R}^m\), and furthermore, since it is not hard to show that \(Q_\epsilon(\cdot, r)\) majorizes \(H_\epsilon(\cdot)\) in the sense that

\[
H_\epsilon(v) \leq Q_\epsilon(v, r)
\]

for any \(v, r \in \mathbb{R}^m\) and \(\epsilon > 0\), it is possible to establish the monotonous decrease of the smoothed \(\ell_p\)-objective at each iteration of IRLS\(_p\) without too much additional work: For each \(t = 1, 2, \ldots\) we obtain that

\[
H_\epsilon^{(t+1)}(r^{(t+1)}) \leq H_\epsilon^{(t)}(r^{(t+1)}) \leq Q_\epsilon^{(t)}(r^{(t+1)}, r^{(t)}) \leq Q_\epsilon^{(t)}(r^{(t)}, r^{(t)}) = H_\epsilon^{(t)}(r^{(t)}),
\]

where the first inequality holds as long as \(\epsilon^{(t+1)} \leq \epsilon^{(t)}\), which is satisfied for the smoothing parameter update rules described in Section 2.2.

The monotonicity outlined in (22) enables the following interpretation of the iterates \(\{x^{(t)}\}_{t \geq 1}\) of IRLS\(_p\): Recalling the definition \(r^{(t)} = Ax^{(t)} - y\), it follows that without any assumption—in
We conclude this section by noting that IRLS can be also interpreted within the framework of majorization-minimization (MM) algorithms—albeit, with the crucial difference that unlike for MM methods, the smoothing updates of IRLS as described in Algorithm 1 change the underlying objective $H_{e(t)}(\cdot)$ every time when $e(t)$ changes, i.e., in many cases at each iteration.

A.2 IRLS$_p$ as Sum-of-Logarithm Minimization for $p = 0$

The considerations of Section A.1 are tailored for IRLS$_p$ with $0 < p \leq 1$. However, it is valid to use IRLS$_p$ with $p = 0$ by setting the weights $w_i^{(t+1)}$ accordingly in (3). In this case, it is still possible to interpret IRLS$_0$ as a smoothing method with respect to an underlying smoothed surrogate objective.

In particular, we then define $H_{e}: \mathbb{R}^m \rightarrow \mathbb{R}$ as in (18) with

$$h_{e}(r) = \begin{cases} \log(|r|), & \text{if } |r| > \epsilon, \\ \frac{1}{2} \epsilon^2 + \log(\epsilon) - \frac{1}{2}, & \text{if } |r| \leq \epsilon, \end{cases}$$

i.e., a smoothed sum-of-logarithm objective [114, 115, 116]. As the inequalities (21) and (22) still hold in this case, we conclude that IRLS$_0$ can be interpreted as a smoothing method for sum-of-logarithm minimization on the residuals $r = Ax - y$. We note that while there is a close relationship between their minimizers, a pointwise majorization of an $\ell_0$-objective $\|Ax - y\|_0$ by the smoothed objective $H_{e}(\cdot)$ as in (19) is not possible for $p = 0$.

Another minor difference to the case $0 < p \leq 1$ is that for $p = 0$, the smoothed objective $H_{e(t)}(r^{(t)})$ of IRLS$_0$ residuals $r^{(t)}$ might converge to $-\infty$ as $\epsilon \rightarrow 0$; however, this is rather a technicality than a deterrence for the numerical performance of the algorithm, which remains excellent.

On the other hand, the local convergence analysis put forward in Section 3.3 and Theorem 2 still applies: In particular, we obtain that IRLS$_0$ as described in Algorithm 1 exhibits local quadratic convergence under appropriate assumptions on the feature matrix, cf. Theorem 2.

B Proofs of Main Results

B.1 Global Linear Convergence for L1-Regression

Proof of Theorem 1. Define $r^* := Ax^* - y$, $r^{(t)} := Ax^{(t)} - y$, and $d^{(t)} := r^{(t)} - r^* = Ax^{(t)} - Ax^*$. Recalling (22), for any $s > 0$ we have the following chain of inequalities:

$$H_{e(t+1)}(r^{(t+1)}) \leq H_{e(t)}(r^{(t+1)}) \leq Q_{e(t)}(r^{(t+1)}, r^{(t)}) \leq Q_{e(t)}(r^{(t)} - sd^{(t)}, r^{(t)})$$

(23)

In (23), the first inequality holds because $\epsilon^{(t+1)} \leq \epsilon^{(t)}$, and $\epsilon \mapsto H_{e}(\cdot)$ is a non-decreasing function in $\epsilon$, the second inequality holds because $H_{e}(\cdot)$ is majorized by $Q_{e}(\cdot, \times)$, see also (22). Furthermore, the third inequality holds due to the optimality of $r^{(t+1)}$ or $x^{(t+1)}$ (cf. (2) and (20)). From (23) we obtain

$$H_{e(t+1)}(r^{(t+1)}) - H_{e(t)}(r^{(t)}) \leq Q_{e(t)}(r^{(t)} - sd^{(t)}, r^{(t)}) - H_{e(t)}(r^{(t)})$$

(24)

$$= \frac{1}{2} \sum_{i=1}^{m} \frac{(r_{i}^{(t)} - sd_{i}^{(t)})^2}{\max\{|r_{i}^{(t)}|, \epsilon^{(t)}\}} - \frac{(r_{i}^{(t)})^2}{\max\{|r_{i}^{(t)}|, \epsilon^{(t)}\}}$$

(25)

$$= s \sum_{i=1}^{m} \frac{-r_{i}^{(t)} \cdot d_{i}^{(t)}}{\max\{|r_{i}^{(t)}|, \epsilon^{(t)}\}} + \frac{s^2}{2} \sum_{i=1}^{m} \frac{(d_{i}^{(t)})^2}{\max\{|r_{i}^{(t)}|, \epsilon^{(t)}\}}.$$  

(26)
We next derive upper bounds for the two sums of (26) respectively. Denote by $S^*$ the support of $r^*$, and define $R := \{i : r^*_i > \epsilon\} \subset \{1, \ldots, m\}$. Then the first sum of (26) is

$$\sum_{i=1}^m -\frac{-r_i^{(t)} \cdot d_i^{(t)}}{\max \left\{ |r_i^{(t)}|, \epsilon(t) \right\}} = \sum_{i \in S^*} -\frac{-r_i^{(t)} \cdot d_i^{(t)}}{\max \left\{ |r_i^{(t)}|, \epsilon(t) \right\}} + \sum_{i \in (S^*)^c} -\frac{-r_i^{(t)} \cdot r_i^{(t)}}{\max \left\{ |r_i^{(t)}|, \epsilon(t) \right\}}$$

$$\leq \sum_{i \in S^*} |d_i^{(t)}| - \sum_{i \in (S^*)^c} \frac{r_i^{(t)} \cdot r_i^{(t)}}{|r_i^{(t)}|} - \sum_{i \in (S^*)^c} \frac{r_i^{(t)} \cdot r_i^{(t)}}{\epsilon(t)}$$

$$\leq (\eta - 1) \sum_{i \in (S^*)^c} |d_i^{(t)}| + \sum_{i \in (S^*)^c} |r_i^{(t)}| - \sum_{i \in (S^*)^c} \frac{r_i^{(t)} \cdot r_i^{(t)}}{\epsilon(t)}$$

The definition of $\epsilon(t)$, from the above we now arrive at

$$\sum_{i=1}^m \frac{-r_i^{(t)} \cdot d_i^{(t)}}{\max \left\{ |r_i^{(t)}|, \epsilon(t) \right\}} \leq (\eta - 1) \sum_{i \in (S^*)^c} |d_i^{(t)}| + \left|(S^*)^c \cap R^* \right| \cdot \frac{\epsilon(t)}{4}$$

$$\leq (\eta - 1) \sum_{i \in (S^*)^c} |d_i^{(t)}| + \frac{\epsilon(t)}{4}$$

$$\leq (\eta - 1) \sum_{i \in (S^*)^c} |d_i^{(t)}| + \frac{1}{4} \sum_{i \in (S^*)^c} |d_i^{(t)}| = (\eta - \frac{3}{4}) \sum_{i \in (S^*)^c} |d_i^{(t)}|.$$  \hspace{1cm} (32)

In the last inequality we used the definitions of $d_i^{(t)}$ and $\epsilon(t)$. Next, the second summation of (26) is

$$\sum_{i=1}^m \frac{(d_i^{(t)})^2}{\max \left\{ |r_i^{(t)}|, \epsilon(t) \right\}} \leq \max_i |d_i^{(t)}| \cdot \sum_{i=1}^m \frac{|d_i^{(t)}|}{\epsilon(t)}$$

$$\leq \eta (\eta + 1) \sum_{i \in (S^*)^c} |d_i^{(t)}| \cdot \frac{(\eta + 1) \sum_{i \in (S^*)^c} |d_i^{(t)}|}{\epsilon(t)}$$

$$\leq \frac{49}{16\eta} \left(\sum_{i \in (S^*)^c} |d_i^{(t)}|\right)^2.$$ \hspace{1cm} (35)

In the above we used $(k, \eta)$-stable RSP multiple times. With the two upper bounds on the sums of (26), and with $s' := s \left(\sum_{i \in (S^*)^c} |d_i^{(t)}|\right)$, we now obtain

$$H_{e^{(t+1)}}(r^{(t+1)}) - H_{e^{(t)}}(r^{(t)}) \leq s' (\eta - \frac{3}{4}) + \frac{(s')^2}{2} \cdot \frac{49}{16\eta} \cdot \frac{\eta}{\epsilon(t)}.$$ \hspace{1cm} (36)

Since $s$ is an arbitrary non-negative integer, let $s$ be such that $s' = (12 - 16\eta)\epsilon(t)/(49\eta)$. Then

$$H_{e^{(t+1)}}(r^{(t+1)}) - H_{e^{(t)}}(r^{(t)}) \leq -\frac{(3 - 4\eta)^2}{98\eta} \cdot \epsilon(t).$$ \hspace{1cm} (37)

The definition of $\epsilon(t)$ (7) implies there exists some $t' \leq t$ such that $\epsilon(t) = \sigma^{(t')}/m$. Substituting this value of $s'$ into the above inequality gives us the bound

$$H_{e^{(t+1)}}(r^{(t+1)}) - \|r^*\|_1 \leq H_{e^{(t)}}(r^{(t)}) - \|r^*\|_1 - \frac{(3 - 4\eta)^2}{98\eta} \cdot \frac{\sigma^{(t')}}{m}.$$ \hspace{1cm} (38)

$$\leq H_{e^{(t)}}(r^{(t)}) - \|r^*\|_1 - \frac{(3 - 4\eta)^2}{98\eta} \cdot \frac{H_{e^{(t')}}(r^{(t)}) - \|r^*\|_1}{3m}.$$ \hspace{1cm} (39)

$$\leq H_{e^{(t)}}(r^{(t)}) - \|r^*\|_1 - \frac{(3 - 4\eta)^2}{98\eta} \cdot \frac{H_{e^{(t)}}(r^{(t)}) - \|r^*\|_1}{3m}.$$ \hspace{1cm} (40)

$$= \left(1 - \frac{(3 - 4\eta)^2}{294\eta m}\right) \cdot \left(H_{e^{(t)}}(r^{(t)}) - \|r^*\|_1\right).$$ \hspace{1cm} (41)
The last two inequalities above are due to Lemma 1 and the monotonicity of \( H_{e(t)}(r(t)) \) in \( t \). Finally, Note that \( H_{e(t+1)}(r(t+1)) \) majorizes \( \| r(t+1) \|_1 \) and Lemma 1 implies

\[
H_{e(t)}(r(t)) - \| r^\ast \|_1 \leq 3\sigma(1) \leq 3 \| r(1) \|_1. \tag{42}
\]

We have thus obtained

\[
\| r(t+1) \|_1 - \| r^\ast \|_1 \leq H_{e(t+1)}(r(t+1)) - \| r^\ast \|_1 \leq \left( 1 - \frac{(3 - 4\eta)^2}{294\eta m} \right) \cdot 3 \| r(1) \|_1. \tag{43}
\]

and the proof is now complete. \( \square \)

**B.2 Local Superlinear Convergence for Lp-Regression**

**Proof of Theorem 2.** We first show that the right inequality of (14), \(\mu \cdot \| Ax^{(t)} - Ax^* \|_1 < 1 \), holds true. With (13) and the definition of \( \mu \), this inequality holds whenever we have

\[
2\eta(\eta + 1)(1 - c)^{p-2} \cdot \min_{i \in S^*} |a_i^T x^* - y_i|^{p-1} \cdot \left( c \cdot \min_{i \in S^*} |a_i^T x^* - y_i| \right)^{1-p} < 1, \tag{44}
\]

\[
\Leftrightarrow 2\eta(\eta + 1)(1 - c)^{p-2}c^{1-p} < 1, \tag{45}
\]

which is true by the definition of \( c \). This finishes proving the right inequality of (14). Next, one easily verifies (14) implies (15). Hence, it remains to prove the left inequality of (14).

Recall \( r^\ast := Ax^* - y \). Define \( r^{(t)} := Ax^{(t)} - y \), and \( d^{(t)} := r^{(t)} - r^\ast = Ax^{(t)} - Ax^* \). And recall that \( S^* \) denotes the support of the ground-truth residual \( r^\ast \). We have

\[
\sum_{i=1}^{m} (r_i^\ast + d_i^{(t+1)}) d_i^{(t+1)} w_i^{(t)} = 0, \tag{46}
\]

a known property for the global minimizer \( x^{(t+1)} \) of the weighted least-squares problem (2). So

\[
\sum_{i=1}^{m} (d_i^{(t+1)})^2 w_i^{(t)} = - \sum_{i \in S^*} r_i^\ast d_i^{(t+1)} w_i^{(t)} \tag{47}
\]

\[
\leq \sum_{i \in S^*} |r_i^\ast| \cdot |d_i^{(t+1)}| \cdot \max \{|r_i^{(t)}|, c^{(t)}\}^{p-2} \tag{48}
\]

\[
\leq \sum_{i \in S^*} |r_i^\ast| \cdot |d_i^{(t+1)}| \cdot |r_i^{(t)}|^{p-2} \tag{49}
\]

\[
= \sum_{i \in S^*} |r_i^\ast| \cdot |d_i^{(t+1)}| \cdot |d_i^{(t)} + r_i^\ast|^{p-2} \tag{50}
\]

\[
\leq \sum_{i \in S^*} |r_i^\ast| \cdot |d_i^{(t+1)}| \cdot |r_i^\ast|^{p-2} \cdot (1 - c)^{p-2}. \tag{51}
\]

In the last step, we used the fact \( |d_i^{(t)}| \leq c \cdot |r_i^\ast| \) for all \( i \in S^* \) (13), which means \( |d_i^{(t+1)} + r_i^\ast| \geq (1 - c)|r_i^\ast| \). Thus, with the definition \( C := (1 - c)^{p-2} \cdot \min_{i \in S^*} |a_i^T x^* - y_i|^{p-1} \), we get

\[
\sum_{i=1}^{m} (d_i^{(t+1)})^2 w_i^{(t)} \leq \sum_{i \in S^*} |d_i^{(t+1)}| \cdot |r_i^\ast|^{p-1} \cdot (1 - c)^{p-2} \tag{52}
\]

\[
\leq C \sum_{i \in S^*} |d_i^{(t+1)}|. \]

From the above and the \((k, \eta)\)-stable RSP, we can now arrive at

\[
\sum_{i \in (S^*)^c} (d_i^{(t+1)})^2 w_i^{(t)} \leq \sum_{i=1}^{m} (d_i^{(t+1)})^2 w_i^{(t)} \leq C \sum_{i \in S^*} |d_i^{(t+1)}| \leq \eta \cdot C \sum_{i \in (S^*)^c} |d_i^{(t+1)}|. \tag{53}
\]

20
Next, from the above and the Cauchy–Schwarz inequality, we get that
\[
\sum_{i \in (S^*)^c} |d_i^{(t+1)}| = \sum_{i \in (S^*)^c} |d_i^{(t+1)}| \cdot (w_i^{(t)})^{\frac{1}{2}} \cdot (w_i^{(t)})^{-\frac{1}{2}} \\
\leq \sqrt{\sum_{i \in (S^*)^c} (d_i^{(t+1)})^2} \cdot \sqrt{\sum_{i \in (S^*)^c} (w_i^{(t)})^{-1}} \\
\leq \sqrt{\eta \cdot C \sum_{i \in (S^*)^c} |d_i^{(t+1)}|} \cdot \sqrt{\sum_{i \in (S^*)^c} (w_i^{(t)})^{-1}}.
\]

We next suppose \(d_i^{(t+1)} = r_i^{(t+1)} - r_i^* \neq 0\) for some \(i \in (S^*)^c\), for otherwise \(r^{(t+1)}\) is \(k\)-sparse and thus \(x^{(t+1)} = x^*\) by the uniqueness of the \(k\)-sparse residual. Then the above inequality implies
\[
\sum_{i \in (S^*)^c} |d_i^{(t+1)}| \leq \eta \cdot C \sum_{i \in (S^*)^c} (w_i^{(t)})^{-1} \\
= \eta \cdot C \cdot \sum_{i \in (S^*)^c} \max \{ |r_i^{(t)}|, \varepsilon^{(t)} \} \cdot |r_i^{(t)}|^{2-p} \\
\leq \eta \cdot C \cdot \left( m \varepsilon^{(t)} \right)^{2-p} + \sum_{i \in (S^*)^c} |r_i^{(t)}|^{2-p} \\
\leq \eta \cdot C \cdot \left( m \cdot \frac{(\sigma^{(t)})^{2-p}}{m^{2-p}} + \sum_{i \in (S^*)^c} |d_i^{(t)}|^{2-p} \right) \\
\leq \eta \cdot C \cdot \left( \frac{1}{m^{1-p}} \cdot \left( \sum_{i \in (S^*)^c} |d_i^{(t)}| \right)^{2-p} \right) \\
\leq \eta \cdot C \cdot \left( \frac{1}{m^{1-p}} + 1 \right) \cdot \left( \sum_{i=1}^m |d_i^{(t)}| \right)^{2-p} \\
\leq 2\eta \cdot C \cdot \left( \sum_{i=1}^m |d_i^{(t)}| \right)^{2-p}.
\]

In the above, we used the definitions of \(\varepsilon^{(t)}, \sigma^{(t)}, r_i^{(t)}, d_i^{(t)}, \) and \(S^*\). We have proved (14) since \(\sum_{i=1}^m |d_i^{(t+1)}| \leq (1 + \eta) \sum_{i \in (S^*)^c} |d_i^{(t+1)}|\) and by the definition of \(C\).

\section{Auxiliary Theoretical Results}

\textbf{Lemma 1 (Upper Bound of The Residual).} Recall \(r^* = Ax^* - y\). Run \(\text{IRLS}_1\) Algorithm 1 with \(p = 1\) and the update rule (7) for \(\sigma^{(t)}\) and \(\varepsilon^{(t)}\), which yields the iterates \(\{x^{(t)}\}_{t>0}\). If \(A\) satisfies \((k, \eta)\)-stable \(\text{RSP}\), then for every \(t \geq 1\) the residual \(r^{(t)} := Ax^{(t)} - y\) satisfies
\[
H_{\varepsilon^{(t)}}(r^{(t)}) - \|r^*\|_1 \leq 3\varepsilon^{(t)},
\]
where \(H_{\varepsilon^{(t)}}(r^{(t)})\) is the smoothed \(\ell_p\)-objective defined in (18) with \(p = 1\).

\textbf{Proof.} Recall \(R := \{i : |r_i^{(t)}| > \varepsilon\} \subset \{1, \ldots, m\}\) and the definition of \(H_{\varepsilon^{(t)}}\) (18), we have
\[
H_{\varepsilon^{(t)}}(r^{(t)}) - \|r^*\|_1 = \sum_{i \in R} r_i^{(t)} + \sum_{i \in R^c} \frac{1}{2} \left( \frac{r_i^{(t)}}{\varepsilon^{(t)}} + \varepsilon^{(t)} \right) - \|r^*\|_1 \\
\leq \|r^{(t)}\|_1 + |R^c| \cdot \varepsilon^{(t)} - \|r^*\|_1 \\
\leq \sigma^{(t)} + \|r^{(t)}\|_1 - \|r^*\|_1.
\]
Then it remains to prove $\|r(t)\|_1 - \|r^*\|_1 \leq 2\sigma(t)$. For this, define $S(t)$ to be the support of the $k$ largest entries of $r(t)$ in absolute values, then $\sum_{i \in (S(t))^c} |r_i(t)| = \sigma(t)$, and we have that

$$\sum_{i \in (S(t))^c} |r_i(t) - r_i^*| \leq \sum_{i \in (S(t))^c} |r_i(t)| + \sum_{i \in (S(t))^c} |r_i^*| = \sigma(t) + \|r^*\|_1 - \sum_{i \in S(t)} |r_i^*|$$

(60)

$$= 2\sigma(t) + \|r^*\|_1 - \|r(t)\|_1 + \sum_{i \in S(t)} |r_i(t)| - \sum_{i \in S(t)} |r_i^*|$$

(61)

$$\leq 2\sigma(t) + \|r^*\|_1 - \|r(t)\|_1 + \sum_{i \in S(t)} |r_i(t) - r_i^*|.$$  

(62)

(63)

Since $A$ satisfies $(k, \eta)$-stable RSP and $r(t) - r^*$ is in the range space of $A$, it holds that

$$\sum_{i \in S(t)} |r_i(t) - r_i^*| \leq \eta \sum_{i \in S(t)} |r_i(t) - r_i^*|$$

(64)

$$\Rightarrow \sum_{i \in S(t)} |r_i(t) - r_i^*| \leq \frac{\eta}{1 - \eta} \left(2\sigma(t) + \|r^*\|_1 - \|r(t)\|_1\right).$$

(65)

In the last inequality we used (63) and rearranged terms. Using (63) and (65) we obtain

$$\|r(t)\|_1 - \|r^*\|_1 \leq \|r(t) - r^*\|_1$$

(66)

$$= \sum_{i \in (S(t))^c} |r_i(t) - r_i^*| + \sum_{i \in S(t)} |r_i(t) - r_i^*|$$

(67)

$$\leq 2\sigma(t) + \|r^*\|_1 - \|r(t)\|_1 + 2 \sum_{i \in S(t)} |r_i(t) - r_i^*|$$

(68)

$$\leq \frac{1 + \eta}{1 - \eta} \left(2\sigma(t) + \|r^*\|_1 - \|r(t)\|_1\right)$$

(69)

which implies

$$\|r(t)\|_1 - \|r^*\|_1 \leq \frac{1 + \eta}{2} \cdot 2\sigma(t) \leq 2\sigma(t).$$

(70)

This finishes the proof. \qed

### C.1 The Stable Range Space Property of Gaussian Matrices

**Proof of Proposition 3.** We need the notion of Gaussian width $w(\cdot)$ of a given set $\mathcal{K}$, defined as

$$w(\mathcal{K}) := \mathbb{E}_{g \sim N(0, I_m)} \left[ \sup_{r \in \mathcal{K}} g^\top r \right].$$

(71)

Write $S^{m-1} := \{v \in \mathbb{R}^m : v^\top v = 1\}$. Denote by $\text{Gr}(n, m)$ the set of $n$ dimensional subspaces of $\mathbb{R}^m$, also known as the Grassmannian manifold or variety. With $\eta \in (0, 1]$, consider the set

$$\mathcal{T}_k := \left\{ r \in \mathbb{R}^m : \sum_{i \in S} |r_i| > \eta \sum_{i \in S^c} |r_i|, \text{ for some } S \subset \{1, \ldots, m\} \text{ with of cardinality } k \right\}.$$  

(72)

The following lemma gives an upper bound on the Gaussian width of $\mathcal{T}_k \cap S^{m-1}$:

**Lemma 2** (Remark 9.30 and Proposition 9.33 of [28]). If $m \geq 2k$ then we have:

$$w(\mathcal{T}_k \cap S^{m-1}) \leq \sqrt{2k \ln(\epsilon m/k)} \cdot \left(1.67 + \eta^{-1}\right).$$

(73)
Lemma 2 and (10) imply that $w(T_k \cap S^{m-1}) \leq \frac{m-n}{\sqrt{m-n+1}}$. Since $A$ has i.i.d. $\mathcal{N}(0,1)$ entries, we can think of its range space $r(A)$ as drawn uniformly at random from the Grassmannian $\text{Gr}(n,m)$. Invoking Lemma 3 with $V = r(A)$ and $M = T_k \cap S^{m-1}$, we see that

$$\Pr(r(A) \cap T_k \cap S^{m-1} = \emptyset) \geq 1 - 2.5 \exp \left( -\frac{1}{18} \left( \frac{m-n}{\sqrt{m-n+1}} - w(T_k \cap S^{m-1}) \right)^2 \right). \quad (74)$$

Furthermore, Lemma 2 and condition (10) make sure that

$$\frac{m-n}{\sqrt{m-n+1}} - w(T_k \cap S^{m-1}) \geq \frac{m-n}{\sqrt{m-n+1}} - \sqrt{2k \ln(em/k)} \cdot (1.69 + \eta^{-1}) \geq \sqrt{18 \ln(2.5\delta^{-1})}. \quad (75)$$

Combining the above leads us to

$$\Pr(r(A) \cap T_k \cap S^{m-1} = \emptyset) \geq 1 - 2.5 \exp \left( -\ln(2.5\delta^{-1}) \right) = 1 - \delta. \quad (77)$$

The event $r(A) \cap T_k \cap S^{m-1} = \emptyset$ implies that the stable $(k,\eta)$-stable RSP holds true.

**Lemma 3** (Gordon’s Escape Through a Mesh Theorem, Corollary 3.4 of [117], Theorem 4.3 of [118]). Let $V$ be an $n$-dimensional subspace of $\mathbb{R}^m$ drawn uniformly at random from the Grassmannian $\text{Gr}(n,m)$. Let $M$ be a subset of $S^{m-1}$. If $w(M) < \frac{m-n}{\sqrt{m-n+1}}$ then

$$\Pr(V \cap M = \emptyset) \geq 1 - 2.5 \exp \left( -\frac{1}{18} \left( \frac{m-n}{\sqrt{m-n+1}} - w(M) \right)^2 \right). \quad (78)$$

## D Experimental Setup

### D.1 How We Run Other Methods

In the real phase retrieval experiment (Figure 2a), all other baselines are implemented in PhasePack [93]. We use the following (quite standard) parameters:

```matlab
opts.tol = 1e-11; opts.initMethod = 'Truncatedspectral';
```

In the experiments of linear regression without correspondences (Figures 2b and 2c), the implementation of PDLP [71] is here, and we run it with the command:

```julia
julia --project=scripts scripts/solve_qp.jl \--instance_path test/trivial_lp_model.mps --iteration_limit 500 \--method pdhg --output_dir [my directory]
```

Note that we run PDLP for a maximum of 500 iterations, while the recommended number of maximum iterations from their GitHub repo is 5000; this is mainly for the sake of efficiency. We use the newest version 9.5.1 of the Gurobi solver with default parameters. we employ the implementation of the FOM toolbox [73] for the (proximal) subgradient descent method. In particular, we invoke the function `prox_subgradient` with the function $G$ being zero and $F$ being $\|Ax - y\|_1$. We use $0$ as initialization, and we observe similar performance when using the least-squares initialization. We set `par.alpha` to $1/\|A\|_2$, which corresponds to a stepsize of $1/\|A\|_2/(t+1)$, where $t$ is the number of iterations. We make this choice because the default `par.alpha = 1` does not work well and sometimes diverges. Finally, we set the maximum number of iterations to be 10000, as the default choice 1000 leads to an estimate with large errors.

### D.2 Synthetic Data Generation

In this section, we provide the Matlab codes generating synthetic data for experiments visualized in Figures 1, 2, and 4, detailing the precise data generation process.

---

The proof of Gordon [117] assumes $M$ to be closed, but this assumption can be removed in view of the definition of the Gaussian width and the compactness of $S^{m-1}$. The factor 3.5 of [117] can be improved to 2.5 [118]. To correct [118]; their condition "$w(S) < \sqrt{F}$" should be replaced by "$w(S) < k/\sqrt{k+P}$."
% robust regression
function [y, A, x] = gen_RR(m, n, k, sigma)
    A = randn(m, n); x = randn(n,1);
    y = zeros(m,1);
    idx = datasample(1:m, k, 'Replace', false);
    y(idx) = randn(k,1);
    s = setdiff(1:m, idx);
    y(s) = A(s, :) * x + sigma * randn(length(s), 1);
end

% linear regression without correspondences
function [y, A, x] = gen_SLR(m, n, sigma, shuffle_ratio)
    A = randn(m, n); x = randn(n,1);
    w = sigma*randn(m, 1);
    y0 = A*x;
    k = int64(shuffle_ratio * m);
    partial_idx = datasample(1:m, k, 'Replace', false);
    y1 = y0(partial_idx, 1);
    y0(partial_idx, 1) = y1(randperm(k));
    y = y0 + w;
end

% real phase retrieval
function [y, A, x] = gen_RPR(m, n, num_positive_sign)
    A = randn(m, n); x = randn(n,1); y = zeros(m,1);
    idx = datasample(1:m, num_positive_sign, 'Replace', false);
    y(idx) = A(idx, :) * x;
    s = setdiff(1:m, idx);
    y(s) = -A(s, :) * x;
    % make y positive
    idx = y < 0;
    y(idx) = -y(idx);
    A(idx,:) = -A(idx,:);
end

E Implementation

The below is our Matlab code that implements IRLS_p:

function [x_hat] = IRLSp(A, y, p, k, num_iter)
    [m, n] = size(A);
    q = 2 - p; l = m - k; epsilon = inf;
    w = ones(m,1); x_old = zeros(n,1);
for i = 1:num_iter
  x_hat = (A' * (w.*A)) \ (A' * (w.* y));
  abs_residual = abs(A*x_hat - y);
  sigma = sum(mink(abs_residual, 1)) / m;
  epsilon = max(min(epsilon, sigma), 1e-16);
  w = 1./ (max(abs_residual, epsilon)).^(q);
  if norm(x_old - x_hat)/ norm(x_hat) < 1e-15
    break;
  end
  x_old = x_hat;
end
